The potency of each C_{17} -polyacetylene compound as a $GABA_A$ antagonist was determined by comparing their ability to inhibit the specific binding of [3H]EBOB (ethynylbicycloorthobenzoate, a specific noncompetitive inhibitor of $GABA_A$ -gated chloride channels that binds to the antagonist picrotoxin-binding site of the $GABA_A$ receptor) to the $GABA_A$ receptor complex in rat brain cortex [20]. Binding studies showed that virol A reversibly reduced $GABA$ -induced chloride current in a noncompetitive, concentration-dependent manner. The [3H]EBOB 50% inhibitory concentration (IC_{50}) values (μM) for cicutoxin, virol A, and picrotoxin were 0.54, 1.15, and 1.81, respectively. In addition, there was a correlation between the potency of the compounds in inhibiting the specific binding of [3H]EBOB to $GABA$ -gated chloride channels of $GABA_A$ receptors in rat brain cortex and their

LD₅₀ values [20]. These observations provide evidence that cicutoxin and related C₁₇-polyacetylenes act as noncompetitive antagonists of the GABA_A receptor by binding to the picrotoxin-binding site within the chloride channel to block ion flow through the channel [32–35].

In an in vitro model, Green et al. [36] incubated human embryonic kidney cells transfected with a plasmid containing cDNA encoding rat GABA_A receptors (which were expressed on the cell surface) with GABA with and without an aqueous extract of *C. douglasii* (containing cicutoxin and other cicutoxin-type compounds). The change in cell membrane potential was then determined for GABA alone (i.e., control or maximal response) and GABA combined with incremental concentrations of the extract (1%, 5%, 10%, 20%). They demonstrated that the extract depressed the maximal GABA response in a concentration-dependent manner (characteristic of noncompetitive antagonism). Pretreatment of 10 mM midazolam was found to reduce the action of the extract.

Binding studies have been performed to measure virol A's effect on the GABA-induced inhibitory chloride current (I_{GABA}). Virol A reversibly reduced I_{GABA} and muscimol-induced chloride current (I_{MUS}) (muscimol is a GABA_A receptor agonist) in rat brain hippocampal CA1 neurons in a concentration-dependent manner. However, it inhibited I_{GABA} in a competitive manner at lower concentrations and in a noncompetitive manner at high concentrations [37]. Other studies showed that virol A further reduced the I_{GABA} already reduced by lower doses of picrotoxin, but not at high doses of picrotoxin, indicating that picrotoxin and virol A may recognize a common binding site [37]. Virol A did not decrease the glycine-induced (glycine is an inhibitory neurotransmitter) current, indicating that it selectively inhibits the GABA response [37]. Virol A was not displaced by [³H]muscimol or by [³H]flunitrazepam in rat brain membrane preparations. Therefore, Virol A apparently binds to a site that is distinct from GABA agonist and benzodiazepine-binding sites [37]. Mice pretreated with subconvulsive doses of cicutoxin had a lower convulsive threshold to picrotoxin, further

suggesting a common, and possibly synergistic, mode of action [31]. Neuroanatomical studies in animals in which the CNS was either destroyed, or severed at different levels, suggest a GABA-antagonism-induced seizure origin in the brain stem [29].

Cardiovascular effects including hypotension, hypertension, bradycardia, tachycardia, ventricular fibrillation, and cardiac arrest have been reported in water hemlock poisoning [6, 7, 11, 12, 18, 26]. However, it is unclear from these case reports whether these cardiovascular effects are secondary to severe seizures or are due to a primary cardiotoxic effect of cicutoxin and/or related toxins found in water hemlock. Studies in anesthetized non-seizing animals have shown that these toxins can cause marked hypotension, usually followed by a hypertensive phase [29, 38]. Bilateral vagotomy, or destruction of the CNS, prevented the bradycardia seen in one of these experiments, but did not affect blood pressure, suggesting a centrally mediated mechanism for bradycardia [38]. However, in both human case reports and animal experiments, these cardiovascular effects have been quite variable, and a mechanism of action has yet to be elucidated.

Parts of *C. maculata* have been used as herbal remedies for scirrhous mammary cancer and cirrhou tumors [39]. Cicutoxin itself has even been studied as a potential chemotherapeutic agent. An extract of *C. maculata* was found to have significant in vitro cytotoxic effects against a human nasopharyngeal cancer cell culture line. Interestingly, structure-activity relationship studies have shown that the same structural moieties responsible for cicutoxin's toxicity (the conjugated double and triple bonds and the two hydroxyl groups) are also responsible for its cytotoxic antileukemic activity [39].

Cicutoxin has also been shown to have activity at voltage-gated potassium channels in stimulated T lymphocytes. Cicutoxin reversibly, and in a potent manner, blocked n-type potassium current in a dose-dependent fashion, thereby inhibiting potassium current-dependent T cell proliferation [40].

In summary, the toxic C₁₇-polyacetylenes responsible for water hemlock's neurological

toxicity inhibit the GABAergic inhibitory chloride current, resulting in decreased inhibitory tone, leading to seizures. They apparently do not have effects at the benzodiazepine and glycine receptors, may share a common binding site with picrotoxin, and may act primarily in the brainstem to cause seizures. They have variable effects on the cardiovascular system. They block voltage-gated potassium channels, are cytotoxic in vitro, and inhibit T cell proliferation. However, it is unclear how each of these effects may contribute to their clinical toxicity.

Clinical Presentation

Water hemlock poisoning typically occurs in persons, often in groups, foraging for edible wild plants. The clinical presentation of water hemlock poisoning was first reported by J.J. Wepfer in 1679 when he described five children who were poisoned after they ingested the plant [41]. The first report of poisoning in North America is attributed to John Stockbridge who published a case of fatal water hemlock poisoning in 1814 [42]. It has since been reported in adults as well as children, and often occurs in the spring when the plants have not yet developed to their full size, and are more likely to resemble other edible wild plants such as ginseng, or wild parsnips, carrots, and turnips. Fatal poisoning in a young woman who ingested water hemlock dropwort roots in the hope that they would be hallucinogenic has also been reported [28]. Egdahl reported a case of water hemlock poisoning as the means of a murder attempt [7]. Egdahl also cites Chevallier in reporting five cases, including two fatalities, of dermal water hemlock poisoning when a family rubbed their skin with the roots of *Cicuta aquatica* in an effort to treat pruritis [7]. It has even been reported that placing slices of *C. virosa* root on the backs of frogs can induce seizures [7]. Frazer [43] reported the deaths of two boys who used the hollow stalk of a hemlock who developed “severe muscular spasms” and died after “blowing the haws (small unripened false fruit) through the stem” for about 3 h. It is unclear from this account whether the hemlock was *Conium maculata*

(poison hemlock) as mentioned by the author or water hemlock (which would be more consistent with the clinical description of “severe muscular spasms” suggesting seizures). As mentioned above, poison hemlock would be associated with flaccid muscle paralysis and death due to respiratory failure, while water hemlock would be associated with seizures (i.e., muscular spasms) and death. However, these cases suggest that fatal poisoning can follow the use of the stalk as a “blow gun,” which would likely involve placing one’s lips on the stalk itself, allowing for absorption of sufficient amount of toxin to cause fatal poisoning [43]. Multiple poisonings can occur when water hemlock is erroneously collected as a presumably edible root and cooked in a meal shared by more than one person. The onset of clinical effects may be delayed and may vary widely in severity among victims. If the meal is not identified as the cause of an index patient’s effects (i.e., seizures), others may actually ingest the meal well after the first patient’s presentation resulting in additional cases of poisoning [44].

The clinical presentation of water hemlock poisoning is essentially identical for either *Cicuta* spp. or *Oenanthe* spp. Initial symptoms are generally gastrointestinal complaints including nausea, vomiting, and abdominal cramping. The onset of symptoms is often within a few minutes, and nearly always within 30–45 min, of ingesting the root but may be delayed several hours [11–13, 15, 16, 18, 26]. Typically, as the amount of the root ingested increases, the time to onset of symptoms decreases, and their severity increases. Vomiting may be significant and repetitive. Other early signs and symptoms include diaphoresis, mydriasis, increased salivation, confusion, dizziness, diarrhea, weakness, ataxia, and hypotension [11–13, 15, 16, 18, 26, 27]. Although mydriasis is typical, miosis has also been reported [26]. Respiratory distress is common, and rales and wheezing have also been reported [6, 7]. The initial symptoms of nausea, vomiting, diarrhea, abdominal cramping, diaphoresis, altered mental status, increased salivation, and weakness are suggestive of a cholinergic toxidrome. Conversely, the mydriasis and seizures are consistent with an anticholinergic toxidrome. There are a number of

poisonous plants that produce cholinergic or anticholinergic toxidromes. Therefore, a careful and complete physical examination is important to avoid mistaking water hemlock poisoning for either cholinergic or anticholinergic poisoning from another cause. The typical presentation is abrupt onset of seizures accompanied by cholinergic-like signs with the notable exception of mydriasis.

The hallmark of water hemlock poisoning is severe, recurrent, and often refractory, generalized seizures. Seizures may occur before or after the vomiting and may even be the initial sign of poisoning. They are most often described as *grand mal*, tonic, tonic-clonic, or status epilepticus. Opisthotonus and hemiballismus have also been reported [6, 12, 45]. Coma, hypotonia, and decreased deep tendon reflexes usually follow seizures [3, 4, 15]. If seizures persist, cyanosis and acidosis develop, and cardiac and/or respiratory arrest may follow. Other reported neurological symptoms include amnesia [2, 12, 26], parathesias [27], neuropsychological abnormalities [6], and hallucinations [12, 44]. Electroencephalograms show diffuse abnormalities that may be persistent [6, 12, 13, 26, 27]. Coagulopathy has been reported on multiple occasions [9, 26].

This author consulted on a group of five boys who ingested varying amounts of the root from a water hemlock plant. They were removing winter overgrowth from a drainage ditch in the springtime. All five developed gastrointestinal symptoms and two suffered seizures. One patient reported visual hallucinations and an “out-of-body” experience en route to the hospital. All patients survived, including the most severely poisoned patient who suffered multiple seizures over approximately 45 min prior to arrival at hospital. He was treated with benzodiazepines, phenobarbital, intubation, and mechanical ventilation and eventually recovered.

Rhabdomyolysis is common in water hemlock poisoning [5, 6, 27]. Patients may complain of muscle pain and tenderness, and creatinine phosphokinase (CPK) values are elevated. This has been noted many times in patients with recurrent seizures and has also been seen in patients in the

absence of seizures, although to a much lesser degree. The etiology of the rhabdomyolysis has not yet been clearly determined. It is likely multifactorial, resulting from seizure-induced muscle activity and breakdown and possibly direct myotoxicity. Therefore, CPK and renal function monitoring is recommended in all patients with water hemlock poisoning. Acute renal failure has also been reported following water hemlock poisoning [5].

Case fatality rates have been reported between 30% and 70%. Cardiopulmonary arrest during status epilepticus is the primary cause of death. This wide mortality range likely reflects, in part, publication bias and that many cases reported in the literature occurred prior to the development of effective anticonvulsant therapy and before the use of modern critical care techniques and advanced life support protocols [7, 9, 10, 22]. However, despite such advances in treatment, water hemlock is still considered the most toxic plant in North America and can be rapidly fatal if not diagnosed early and treated aggressively [11, 13, 28].

Diagnosis

The diagnosis of water hemlock poisoning must be made on the basis of history and clinical presentation. There are no easily available diagnostic tests. Table 1 lists critical features that should be elucidated in the history of possible water hemlock ingestion.

Table 1 Historical features of importance in the diagnosis of water hemlock poisoning

Detailed description of the ingested plant, including the locale in which it was found (if possible, the plant itself should be obtained for identification)
The part and amount of the plant ingested
Time of ingestion
History of any coingestants
History of all signs and symptoms since ingestion (<i>N.B.</i> patient may present obtunded and unable to provide history)
Other possible victims

The cholinergic-like manifestations, such as emesis, abdominal cramping, excessive salivation and lacrimation, diaphoresis, and seizures, may lead some to suspect poisoning by grayanotoxin-containing plants such as death camas (*Zigadenus* spp.), mountain-laurel (*Kalmia latifolia*), azalea, or *Rhododendron* (*Rhododendron* spp.). Death camas has been mistaken for wild onion by people foraging for edible wild plants. Identification of the ingested plant should help differentiate water hemlock from these species. Other poisonous plants found in the United States that cause seizures include black cherry (*Prunus serotina*), jimson weed (*Datura stramonium*), black nightshade (*Solanum nigrum*), and sneeze weed (*Helenium autumnale*) [7]. Jimson weed and nightshade present with an anticholinergic syndrome, including marked mydriasis, but should not have the cholinergic manifestations reported with water hemlock poisoning. Black cherry is a cyanogenic plant and produces significantly delayed effects, including vomiting, abdominal pain, coma, and seizures, whereas water hemlock poisoning typically develops soon after ingestion of the plant.

Water hemlock often grows in drainage ditches, which may contain irrigation runoff contaminated with organophosphate (OP) pesticides. Organophosphate (or, similarly, carbamate) pesticide poisoning also produces a cholinergic toxidrome similar to the symptoms seen in water hemlock poisoning. Therefore, OP poisoning should be considered in the differential diagnosis of the poisoned patient with cholinergic symptoms in an agricultural setting. However, the marked mydriasis seen in water hemlock poisoning would be inconsistent with a cholinergic agent. Also, these pesticides produce profuse *atropine-responsive* bronchorrhea, a feature that is not seen in water hemlock poisoning.

As discussed earlier, it is important not to confuse the water hemlock plant with the closely related poison hemlock (*Conium maculatum*), which has a similar appearance. The active toxins in poison hemlock, coniine, N-methyl coniine, conhydrine, λ -coniceine, and pseudoconhydrine, are structurally similar to nicotine and bind to nicotinic receptors. Toxicity from water hemlock

manifests primarily as vomiting and seizures within an hour of ingestion. Although poison hemlock poisoning may initially present with nausea, vomiting, and abdominal cramping, like water hemlock, this initial stimulatory phase is followed by an ascending paralysis, CNS depression, and bradycardia and death from respiratory paralysis. ► [Chapter 113, “Poison Hemlock”](#) provides a complete discussion of poisoning by that plant.

In summary, the diagnosis of water hemlock poisoning is based upon the identification of the plant ingested, a clinical presentation that includes signs and symptoms suggestive of cholinergic poisoning, mydriasis, and abrupt onset of severe seizures. The differential toxicologic diagnosis should include other toxic plants that produce similar manifestations, and OP/carbamate pesticide poisoning if the ingestion occurs in an agricultural setting, or other conditions that suggest such a pesticide exposure.

Treatment

There is no specific antidote for water hemlock poisoning. Management should focus on cardiopulmonary stabilization, control of seizures, and gastrointestinal decontamination. Aggressive airway management, if indicated, is the initial treatment priority as these seizing patients are at high risk for aspiration, hypoxia, and anoxia. Stability and security of the airway should be assured.

Patients will often theoretically partially self-decontaminate with repeated bouts of vomiting that may occur following water hemlock ingestions. However, given the extremely high toxicity of even a small amount of ingested plant material, if the patient presents for treatment early, prompt attempts at decontamination by the administration of activated charcoal should be performed without delay if the patient presents within the first hour or 2 after ingestion. However, these measures have not been shown to alter the outcome, or clinical course, of water hemlock-poisoned patients or even poisoned patients in general. The usual dose of activated charcoal is 50 g orally in adults and 1 g per kilogram in children. Since these

patients are prone to develop diarrhea, cathartics should not be administered with the activated charcoal. If charcoal is to be administered, due to the risk of seizures, the patient's mental status and ability to protect their airway must be assessed prior to the administration of activated charcoal. If the patient is unable to protect their airway, then intubation is indicated.

Although not studied in clinical trials, benzodiazepines, barbiturates, and propofol are the appropriate treatment of water hemlock-induced seizures based on cicutoxin's stimulatory effect on GABA_A receptors. The seizures seen in water hemlock poisoning are often refractory to treatment. Therefore, these anticonvulsants should be administered aggressively and as promptly as possible after onset of seizures. Anticonvulsant dose should be titrated to effect with the end point of seizure control. Intubation should also be considered early with the use of high or repeat doses of benzodiazepines and/or barbiturates and/or decreased mental status. Phenytoin has been shown to be less effective than phenobarbital in controlling cicutoxin-induced seizures in an animal model and should not be used [31]. Although water hemlock poisoning has many features of a cholinergic toxidrome, an animal study found that water hemlock-induced seizures were not suppressed by pretreatment with anticholinergic agents benztropine or biperiden, nor worsened by the cholinergic agonist physostigmine, but were well controlled with diazepam [46, 47]. In an animal study, Panter et al. [48] found that in sheep given 1.5–2.5 times the lethal dose of water hemlock (*C. douglasii*) by gavage, intravenous administration of sodium pentobarbital at the onset of the first seizure prevented further seizures and skeletal and cardiac muscle degeneration and resulted in rapid and complete recovery [48].

Rhabdomyolysis may be severe and may be treated with intravenous fluids and/or urine alkalization to maintain good urine output and minimize the risk of myoglobin-induced renal failure. If so chosen, urine alkalization (pH > 6.5) can be achieved by adding 50–100 mEq of sodium bicarbonate to 1 l of dextrose in water (D5W), or up to 0.5 normal saline, and administering this intravenously at approximately 1.5 to two times

the maintenance rate. Acute oliguric renal failure due to water hemlock poisoning with rhabdomyolysis has been treated with short-term hemodialysis [5].

Extracorporeal Elimination

The use of hemodialysis and hemoperfusion as treatment for water hemlock poisoning has been reported in a 30-year-old man who was also treated with gastric lavage, oral activated charcoal, urine alkalization, forced diuresis, paralysis, mechanical ventilation, and physostigmine [12]. The patient recovered, although it is unclear as to what impact, if any, the use of extracorporeal elimination techniques had on his outcome. Therefore, except for the supportive treatment of acute renal failure, there are insufficient data to recommend hemodialysis and/or hemoperfusion in the treatment of water hemlock poisoning.

Special Populations

Water hemlock poisoning should be suspected in patients with vomiting and recurrent seizures with a history of wild plant ingestion, camping, or foraging. No populations have been reported either as more, or less, susceptible to water hemlock poisoning.

Indications for ICU Admission

- Any clinically affected patient with a history of water hemlock ingestion
- Any patient requiring anticonvulsants for treatment of seizures after water hemlock ingestion

Common Pitfalls

- Misdiagnosis as either anticholinergic poisoning (due to mydriasis) or cholinergic poisoning (due to increased secretions,

(continued)

nausea, vomiting, diarrhea, abdominal cramping, and seizures)

- Failure to aggressively manage the patient's airway and cardiorespiratory status
- Failure to use benzodiazepine and/or barbiturate anticonvulsant medications aggressively (e.g., lorazepam, phenobarbital)

Criteria for ICU Discharge

- Resolution of seizure activity without ongoing anticonvulsant administration
- Resolution of acidosis (if previously present)
- Normal mental status

Key Points

- Rapid identification of ingested plant (if possible)
- Early and aggressive management of airway and cardiopulmonary status
- Early and aggressive management of seizures
- Monitoring for rhabdomyolysis

Scorpions are the second most globally important cause of envenoming, after snakebite and in some regions are more important than snakebite. Estimates have been made of the incidence of medically significant scorpion stings (Table 1) [1]. Scorpion sting is a significant problem principally in regions within the two tropics, notably in more arid areas (Fig. 1) [1]. All scorpions are venomous, with a sting structure in the “tail” (telson) [1–4]. However, only a minority of scorpion species are known to cause medically significant envenoming in humans, and virtually all of these are found in a single family, Buthidae, and cause systemic envenoming that can prove lethal, particularly in children [1–4]. There is an important outlier, the Iranian species *Hemiscorpius lepturus*, family Hemiscorpidae (formerly in family Scorpionidae), which has a very different clinical envenoming profile [5–7]. At least two other genera of scorpions have occasionally been reported as causing medically significant stings: *Heterometrus* spp. and *Nebo* spp., family Scorpionidae (*Nebo* is placed within family Diplocentridae by some taxonomists) [8–11]. With the exception of *Hemiscorpius* and a few other species, scorpion stings cause immediate pain, often severe, occasionally nonspecific systemic symptoms, and, in the case of medically important species, a variable syndrome of neuroexcitatory systemic envenoming. This latter group has generally been considered homogenous in clinical presentation, but as more detail is collected on the effect of stings by individual species, it is

approximate incidence of stings is 1 to 100/100,000 population. Those areas in dark red approximate incidence of stings >100/100,000 population (Figure copyright © Julian White 2016)

becoming apparent that there are distinct envenoming syndromes associated with each group, sometimes even species, of scorpion.

Taxonomy

Scorpions are invertebrates, arthropods, with four pairs of legs, the distinctive chelicerae (front “pin-cers” or “claws”), multiple eyes, and the defining “tail” with the terminal segment containing the venom gland and sting [4]. As a general rule,

scorpions with bulky pincers (chelicerae) use these to help capture and subdue prey and rely less on potent venom, so that for humans, their sting, though generally painful, is less likely to result in significant envenoming [12]. Conversely, those scorpions with comparatively delicate pin-cers often rely more on potent venom, so are more commonly associated with significant en-venoming in humans [12].

There are approximately 18 families of scor-pions (Table 2), with approximately 2,000 described species at last count, with numerous

new species being described each year, reflecting a concerted effort by scorpion taxonomists to catch up with the backlog of undescribed, but known, species, although there is significant controversy surrounding scorpion taxonomy [13]. All medically important species fall within just four families, Buthidae, Hemiscorpiidae (Scorpionidae), Diplocentridae (subsumed within Scorpionidae by some taxonomists), and Scorpionidae, though many other species of scorpion can deliver distressing locally painful stings, but without significant systemic effects.

The Anatomy of Scorpions is Distinctive

Family Buthidae

While the vast majority of medically important scorpions are in family Buthidae, they are found in only some genera (Table 2), and there are numerous Buthid scorpions which have not been reported as causing medically significant stings (Fig. 2) [1, 2]. Some of the most medically important genera include:

Genus *Androctonus*

These scorpions, found predominantly in North Africa through to the Middle East, include several species of known medical significance (*A. australis*, *A. bicolor*, *A. crassicauda*, *A. mauritanicus*), and it is possible other *Androctonus* spp. may cause medically significant stings [1, 2]. Recent taxonomic studies have indicated that even within currently defined species, such as *A. australis* (Fig. 3), there may be several distinct populations, and the implications of this for venom toxicity and clinical profile are unclear [14]. In Morocco it appears *Androctonus* spp. are responsible for many, possibly a majority of medically significant stings, with 30–50,000 cases reported to the Moroccan Poison Information Center (PIC) annually, of which about 1,000 are severe, with 10–100 fatalities/year [1]. However, the Moroccan PIC data includes stings by other species, and among these, *Buthus occitanus* is of major significance. It should be noted that appropriate anti-scorpion antivenom is generally not available in Morocco, so it is unclear if ready availability of antivenom might reduce the number of fatalities. Past studies in Morocco reported that *A. mauritanicus* was the principal species involved and clinical

Fig. 3 *Androctonus australis* from North Africa (Figure copyright © Julian White 2016)

improvement was noted with specific antivenom treatment, compared to patients not given antivenom, but in a nonclinical trial study [15, 16]. In Algeria *A. australis* is reported to cause 70% of medically significant stings [17]. In Libya *A. australis*, *A. bicolor*, and *A. amoreuxi* all occur, but it is unclear if all cause medically significant stings [18]. In Saudi Arabia *A. crassicauda*,

together with *Leiurus quinquestriatus*, is considered the most medically important scorpion [19]. In Turkey *A. crassicauda* is responsible for most medically significant scorpion stings, >50% in one series [20]. In Iran *A. crassicauda* is considered of major medical significance, second only to *Hemiscorpius lepturus* in severity and lethal potential [21].

Genus *Buthus*

At least *Buthus (occitanus) tunetatus* and *B. occitanus* (Fig. 4) may cause medically significant stings [15, 16, 22, 23]. The latter species, widely distributed in parts of Mediterranean Europe and North Africa, appears to have distinct differences in venom and clinical severity within the geographic range [1, 24]. While most stings may be painful, significant or severe systemic envenoming appears largely restricted to some North African populations such as those in Morocco.

Genus *Centruroides*

It is likely many species of *Centruroides* scorpions may cause medically significant stings, particularly in children, though only a limited range

of species are clearly hazardous (*C. sculpturatus* (Fig. 5), *C. noxius*, *C. suffusus*, *C. infamatus*, *C. limpidus*) [1–3, 25–27].

Genus *Hottentotta*

These scorpions range from Africa to the Indian subcontinent and include at least several species of major medical significance (*H. alticola*, *H. hottentotta*, *H. tamulus* (note *H. tamulus* was previously named *Mesobuthus tamulus*)) [1, 2, 28]. The taxonomy of this group of scorpions has been the subject of revision [29]. While the medical importance of stings in Africa appears to be minor, in the Indian subcontinent *H. tamulus* is arguably the most medically important Indian scorpion [1, 28, 30].

Genus *Leiurus*

Possibly all *Leiurus* spp. scorpions are medically important, not just the well-recognized and feared *L. quinquestriatus* (Fig. 6) [1, 2, 31]. While principally recognized from North Africa through to the Middle East, it is also reported as present and causing major envenoming in sub-Saharan Africa [31]. While the majority of stings are non-life threatening, in children severe and potentially fatal envenoming can occur and is occasionally reported in adults [1, 31–34]. In at least part of the range of *L. quinquestriatus*, it is reported to commonly cause acute pancreatitis in children [35].

Genus *Mesobuthus*

The medical importance of *Mesobuthus* spp. scorpions is less clear since the known important

Fig. 4 *Buthus occitanus* from North Africa (Figure copyright © Julian White 2016)

(Figure copyright © Julian White 2016)

species, *M. tamulus*, was shifted to genus *Hottentotta*, as *H. tamulus* [1, 28–30].

Genus *Odontobuthus*

The medical importance of this genus and specifically *O. doriae* remains unclear, but limited clinical case experience in Iran indicates this species can cause, in addition to moderate to marked local pain, some systemic effects including tachycardia and pulmonary edema [21].

Genus *Parabuthus*

These sub-Saharan African scorpions include several species of medical significance (*P. transvaalicus*, *P. granulatus*, possibly *P. liosoma*, *P. mossambicensis*) (Fig. 7) [1, 2, 36–39].

Fig. 7 *Parabuthus transvaalicus* from Southern Africa
(Figure copyright © Julian White 2016)

Genus *Tityus*

Arguably the most medically important genus of South American scorpions, *Tityus*, includes a number of species causing major envenoming frequently in parts on the continent, notably, but not exclusively, Brazil (*Tityus serrulatus*, *T. bahiensis*, *T. pachyurus*, *T. zulianus*, *T. confluens*, *T. asthenes*, *T. breweri*, *T. stigmurus*, *T. obscurus*, *T. trivittatus*, *T. neoespartanus*, *T. trinitatis*) [1, 2, 40–54]. At least one species, *T. serrulatus*, is parthenogenetic (Fig. 8) [55].

Family Hemiscorpiidae

Genus *Hemiscorpius*

H. lepturus is clearly associated with medically important stings in southwestern Iran, where it is a leading cause of severe and lethal envenoming [1, 5–7, 21, 56–63]. It is also reported from Iraq, Yemen, and Pakistan, but it is unclear if it causes significant human envenoming in these locations. As mentioned earlier, the envenoming profile is

Fig. 8 *Tityus serrulatus* from Brazil, South America (Figure copyright © Julian White 2016)

very distinct from that caused by Buthid scorpions and is more closely clinically aligned with the necrotic arachnidism resulting from bites by brown recluse spiders, *Loxosceles* spp. [64].

Family Scorpionidae

Genus *Nebo*

Nebo hierichonticus has been reported to cause medically significant envenoming, more closely related to *Hemiscorpius lepturus* envenoming than Buthid-type envenoming, but few case reports are available to properly define the envenoming syndrome, and the epidemiologic importance of these scorpions remains uncertain [8]. A single case report documented intracranial and retinal hemorrhages in a child, which resolved without residual deficit [11].

The medical significance of stings by the widely distributed Asian scorpion genus *Heterometrus* remains unclear [8], though venom studies indicate at least some species have neurotoxic venoms (*H. longimanus*, *H. spinifer*; direct agonist actions on postjunctional muscarinic M3 cholinergic receptors and alpha-adrenoceptors) [65]. However, there is no clear evidence to verify any species causing medically significant stings.

Scorpion Venoms

Venom research into scorpions has concentrated on Buthid venoms which have proved a rich source of highly potent and often very specific ion channel toxins, particularly potassium channel toxins [3, 4]. These diverse small peptide toxins can target just a few, sometimes just one type of ion channel and so have proven instrumental in understanding the molecular basis of neural signaling pathways [4, 66, 67]. Scorpion toxins are divided into two broad classes of short chain peptides by some authors [4]:

1. The “long toxins,” with about 60 AA, target principally Na^+ channels and are considered as dominant in causing clinical envenoming in humans and divided into two subgroups. Alpha-type toxins found principally in Paleotropical species inhibit the inactivation phase of the nerve action potential, binding to site 3 on the Na^+ channel. Beta-type toxins are found in Neotropical species and reduce the excitability threshold of excitable cell membranes acting at site 4 of the Na^+ channel. For the most medically important scorpions of family Buthidae, usually only one type of long toxin is found, alpha or beta.
2. The “short toxins,” with about 30–40 AA, target principally K^+ or Cl^+ channels and are often present in only small quantities in scorpion venom. They occur across all types of scorpions. The K^+ channel short toxins can be subdivided into voltage-dependent and ligand-dependent types, and all have 3–4 disulfide bridges with a CSab motif and are of most importance as pharmacologic tools. They are generally nontoxic in mammals, except if injected intracerebrally.

In contrast to snake venoms, most scorpion venoms and specifically Buthid venoms are richly endowed with polypeptide toxins, but generally have few or no enzymatic toxins [4].

The toxins involved in the local necrotic and systemic hemolytic and organ destructive effects

of *Hemiscorpius lepturus* venom have been less well defined, in part because this species has a very limited geographic range, mostly in western Iran, and venom may be less easy to obtain for study. In vivo studies of whole venom in mice indicated it is highly cytotoxic, damaging the myocardium and renal tubules by 3 h postinjection, followed by intestinal damage by 6 h, with elevated creatine kinase and lactate dehydrogenase, but no observed effects on the lungs or liver [68]. The venom can induce the immune system to produce interleukin-12 [69]. Envenoming is associated with ADAMTS13 deficiency and ADAMTS13 autoantibody in human cases, and it has been suggested that this may play a role in venom-induced coagulopathy and development of both DIC- and an HUS-like syndrome [70]. The role of a sphingomyelinase-D-like toxin, Heminecrolysin, has been emphasized in some studies, interestingly given a similar toxin that is considered a major factor in recluse spider, *Loxosceles* spp., venom-induced local necrosis. Indeed there are significant similarities between *Hemiscorpius lepturus* envenoming and *Loxosceles* envenoming (loxoscelism) [71, 72]. Heminecrolysin has potent lysophospholipase-D activity, and this may play an important role in intravascular hemolysis in envenomed patients [73].

Scorpionidae scorpion toxins have also been examined for a limited range of species, notably from the two genera of possibly medically significant scorpions, *Nebo* and *Heterometrus* [65, 74–76]. The latter, in at least some species, contains a variety of components including peripheral muscarinic agonist toxins, ion channel toxins, phospholipase A₂ toxins, antibacterial toxins, and anti-osteoporosis agents [65, 76].

Clinical Presentation

Some key groups of scorpions will be covered in detail in subsequent chapters. As discussed earlier, most medically important scorpions cause predominantly neuroexcitatory envenoming, in addition to local pain [3, 4]. A summary of clinical features is listed in Table 2.

There are two broad types of clinical syndromes associated with scorpion envenoming:

1. Neuroexcitatory envenoming characterized by an initially painful sting, often severely painful, followed by development of systemic envenoming in patients where sufficient venom has been injected. Because of smaller body mass, children are more likely to develop severe or life-threatening envenoming. As with any other type of envenoming, not all patients will suffer significant envenoming, and in adults, for most scorpion species, envenoming is an unpleasant but time-limited and survivable illness. Neuroexcitatory envenoming by scorpions is predominantly a feature of selected Buthid (family Buthidae) scorpions. Many other scorpion species may cause significant, usually short-lived local pain, but without specific neuroexcitatory envenoming. Within this broad group there are clinical features specific for particular species groups, though delineation of such syndromes is generally rudimentary or incomplete in most cases at this time. Features common across many Buthid species groups include autonomic stimulation (a catecholamine-storm-like effect; hypertension, tachycardia, piloerection, sweating, salivation, etc.), cardiac dysfunction (reduced output, cardiac failure, raised troponins, cardiogenic pulmonary edema), neurologic effects (collapse, in some cases convulsions, coma, or athetoid movements of limbs or nystagmus), and nonspecific effects such as abdominal pain, headache, nausea, and vomiting [3, 4].
2. Dermonecrotic envenoming with systemic cytotoxic effects. This type of envenoming is rare for scorpion stings and is mostly seen with Iranian *Hemiscorpius lepturus* envenoming, particularly in the Khuzestan region of SW Iran [5–7, 21, 56–63]. The sting may not be painful and can go unnoticed, with later development of local skin necrosis and a systemic illness which, in severe cases, includes intravascular hemolysis, anemia, thrombocytopenia, disseminated intravascular coagulation, acute kidney injury (AKI) and renal failure, multi-organ failure, and death [5–7]. As for

neuroexcitatory scorpion envenoming, children are at highest risk [6]. In a study of envenomed children with hemolysis and hematuria, 23% had AKI, 6.7% developed DIC, and 10% developed a hemolytic uremic-like syndrome, and within this entire pediatric patient group, 98% had detectable anti-ADAMTS13 antibody, and 92% had decreased levels of ADAMTS13 [70]. *H. acanthocercus* has recently been reported as causing similar envenoming in Iran, with a confirmed fatality. It is unclear how many other *Hemiscorpius* spp. may be medically significant [63].

A group named the Scorpion Consensus Expert Group has proposed a unified clinical classification of scorpion envenoming, although this classification ignores dermonecrotic envenoming, concentrating on just neuroexcitatory envenoming, and the group is dominated by members from Morocco and France [77]. The “final proposed classification” of severity of scorpion stings, essentially a grading system, is presented in Table 3.

Treatment

The treatment of scorpion stings and of cases with significant envenoming remains controversial globally, with two distinctly different approaches advocated by groups of clinicians.

The intensive care and pharmacologic approach:

This approach is based on the assumption that antivenom, as a specific antidote, is ineffective in scorpion envenoming and that supportive care and standard pharmaceuticals are more effective. This view has been prominent across parts of North Africa, the Middle East, and the Indian subcontinent and is applicable only to classic neuroexcitatory scorpion envenoming; it has not been proposed for dermonecrotic envenoming [78–87].

The use of ICU and life-supportive measures such as inotropes, IV fluids, intubation, and ventilation, all where indicated, has been reported as effective in treating severe scorpion stings in both Israel and India and more

recently in parts of North Africa including Morocco, Algeria, and Tunisia [78–87]. The latter three countries, at least, had previously relied on use of antivenom, and it is unclear the validity of studies suggesting antivenom was less effective [84–86]. In India the advent of a specific scorpion antivenom has seemingly modified this approach, so that antivenom is now the preferred treatment in most centers [88–93].

The antivenom-centric approach:

Globally this is the predominant preferred treatment. There is ample published evidence that when used appropriately it results in better outcomes for patients and reduced mortality [17, 22, 23, 88–110]. In Mexico alone, with about 300,000 hospitalizations per year for scorpion sting, the advent of antivenom has dramatically reduced mortality in the prime risk group, children [95, 97].

The dose of antivenom will depend on the type of antivenom and the degree of envenoming, not the size of the patient. Scorpion venoms can rapidly distribute throughout the body, and systemic envenoming can develop rapidly; therefore antivenom should be given very early to have maximum benefit, with significant decreasing value as the time from sting to administration increases [17, 23, 101, 104]. (Grade IIa recommendation) It is unclear at what point giving antivenom is no longer appropriate, but certainly after 24 h it is likely to be much less effective. Nevertheless, in a patient with life-threatening envenoming, where other treatment modalities are also proving of limited effectiveness, active consideration to giving appropriate antivenom at a high dose is appropriate.

As in any other situation where antivenom is used, there is a risk of adverse reactions, and appropriate precautions should be taken, including having adrenaline (epinephrine) drawn up ready to give, if required, plus having resuscitation equipment immediately to hand.

It is important to note that for dermonecrotic scorpion envenoming by *Hemiscorpius lepturus*,

Table 3 A grading system for neuroexcitatory scorpion envenoming proposed by the “Scorpion Consensus Expert Group” [77]

Class I: local manifestations	Class II: minor manifestations (non-life threatening)	Class III: severe manifestations (life threatening). Presence of at least one of the following signs
Bullous eruption Burning sensation Ecchymosis Erythema Hyperesthesia Itching Necrosis paresthesia Pain Purpura/petechia Swelling Tingling	Abdominal distension Agitation/restlessness/excitement Anisocoria Arthralgia Ataxia Confusion Convulsion Diarrhea Dry mouth Dystonia Encephalopathy Fasciculation Gastrointestinal hemorrhage Hematuria Headache Hypertension Hyperthermia Hypothermia Lacrimation Local muscular cramps Miosis Mydriasis Myoclonia Nausea Nystagmus Odynophagia Pallor Pancreatitis General paresthesia Priapism Prostration Ptosis Rhinorrhea Salivation Somnolence/lethargy/drowsiness Stridor Sweating Tachycardia Thirst Urinary retention Vomiting Wheezing	Cardiogenic failure Hypotension Ventricular arrhythmia Bradycardia Cardiovascular collapse Respiratory failure Cyanosis Dyspnea Pulmonary edema Neurological failure Glasgow score ≤ 6 (in absence of sedation) Paralysis

antivenom is the current cornerstone of treatment, and there is no apparent dissent from its use in patients with this form of envenoming [21, 56–60]. The previously discussed non-antivenom approach to treatment of scorpion stings is entirely inappropriate for this form of envenoming. Studies have

demonstrated effectiveness of the antivenom in an in vivo rat model, even when administered 2 h post-venom [56]. Experimentally, a camelid nanobody antibody fragment-based antidote has been successfully developed against *Hemiscorpius* venom, but the role of this in future clinical use is untested [111].

Scorpion Antivenoms

A number of antivenoms against particular scorpion venoms are produced in South and Central America, Africa, the Middle East, Europe, and India [112]. In a number of regions/countries, Mexico being a good example, the introduction of scorpion antivenom has been associated with a dramatic improvement in outcomes [3, 27]. However, in certain regions and countries, there has been a move away from antivenom as a treatment choice, and the literature is replete with arguments in favor, or against, the use of antivenom, as noted earlier [17, 22, 78–80, 84–86, 98, 101, 103–105].

However, the availability of an effective antivenom may not equate with advocacy for routine use in envenomed patients because other factors, notably cost, may negatively influence the cost/benefit equation, a situation recently discussed in relation to treating scorpion envenoming in the USA [110].

Non-antivenom treatments

As noted earlier, non-antivenom treatment of scorpion stings has been advocated by a number of groups, mainly in North Africa, through the Middle East, to India, but in at least some of these places, notably India, now antivenom is available, the same authors who earlier advocated non-antivenom treatment now advocate use of antivenom [78–93]. This needs to be considered when perusing the often confusing literature on management of scorpion envenoming.

However, it is clear that treatments such as the use of prazosin can be effective in managing scorpion envenoming and should be considered when antivenom is not readily available [87–92]. Equally, such pharmacologic approaches may have a useful adjunctive role in treatment.

Conclusion

Scorpion stings are an important cause of injury from venomous animals globally and represent the second most important impact, after snakebite.

In some regions scorpion sting is more important than snakebite in impact on the health system. Only a small minority of scorpions can cause significant envenoming, and most of these are Buthid scorpions causing systemic and potentially lethal neuroexcitatory envenoming, in addition to marked local pain. An important outlier is the Iranian scorpion, *Hemiscorpius lepturus*, which causes delayed local necrosis and a potentially fatal cellulolytic systemic syndrome of hemolysis, DIC, and multi-organ failure, similar to loxoscelism caused by recluse spiders. Despite ongoing controversy, the available evidence, globally, favors the use of specific antivenom as the most effective treatment for systemic scorpion envenoming, but this is most effective when given early.

Scorpions are arthropods with a hard exoskeleton, two anterior pinching claws, and a tail ending with a bulbous enlargement. The poison gland and the stinger are located at the distal part of the tail. The tail is long and able to arch over the head, allowing the stinger to hit the prey grasped between the claws [1]. Scorpions are among the oldest creatures on earth. Their habitat is warm and arid areas, as reflected in their first mentioning in the Bible: “He led you through the vast and dreadful desert, that thirsty and waterless land, with venomous snakes and scorpions” [2]. The scorpion is a nocturnal animal that hibernates in winter and is active in the warm seasons [3].

Epidemiology

Scorpion sting is common and endemic in various regions. Because most envenomations occur in developing countries, where regular reporting systems often are lacking, data on scorpion stings in several countries are based on estimates. High fatality rates were reported from scorpion envenomation from Saudi Arabia, Israel, Tunisia, Egypt, and Iran in the 1960s and 1970s. In recent years, there has been a marked reduction in mortality, however, owing to the improvement in supportive care and increased availability of antivenom therapy.

In a report by Chippaux and Goyffon from 2008, the estimated annual number of scorpion stings exceeded 1.2 million globally, with more

Table 1 Scorpion envenomation by species, regions, and characteristic toxicity

Scorpion species	Geographic region	Cardio-toxicity	Neuro-toxicity	Hemolysis DIC, renal failure cytotoxicity	Reference
<i>Leiurus quinquestriatus</i>	Middle East, Turkey	+++	++		[14–20]
<i>Androctonus crassicauda</i> , <i>A. australis</i> , <i>A. mauretanicus</i>	Middle East and North Africa, Turkey, Iran	+++	++		[5–11, 20, 24, 27]
<i>Buthus occitanus</i>	North Africa	+++	+		[6]
<i>Hemiscorpius lepturus</i>	Iran, Iraq	+	+	++	[23, 25–29]

Fig. 1 The scorpion *Leiurus quinquestriatus*

than 3,250 deaths (0.27%). Middle Eastern and North African scorpion stings accounted for 42% of the global sting burden and a half of the fatalities. The number of scorpion stings in the Middle East and North Africa was estimated at 146,500 and 350,000, respectively [4]. The case-fatality rates were estimated at 0.42% and 0.52%, respectively, but these estimates are imprecise due to incomplete information.

Scorpion species of medical importance in the Middle East and Africa have been mainly reported from Tunisia, Morocco, Egypt, Israel, Saudi Arabia, Turkey, and Iran, though likely occur across all countries in North Africa and the Middle East [4–28]. Some of the main venomous scorpions, their geographic distribution, and target organ toxicities are listed in Table 1.

The main offending toxic scorpion in the Middle East, *Leiurus quinquestriatus* is illustrated in Fig. 1.

Some of the major clinical series of scorpion envenomations reported from Middle East and North African countries are listed in Table 2.

Biochemistry and Pathophysiology of Scorpion Envenomation

Scorpion venom is a complex mixture of mucopolysaccharides, hyaluronidase, serotonin, histamine, protease inhibitors, histamine releasers, neurotoxins, and approximately 70 polypeptides. Despite species differences, there are some similarities in venom composition; this explains some similarities among clinical manifestations in envenomation sustained from scorpion stings from different geographic locations [30].

Scorpion venom increases neuronal Na^+ influx by blocking inactivation of the Na^+ channel, resulting in increased duration and amplitude of the neuron action potential (Fig. 2). Consequently, a voltage-gated channel opening is enhanced by increased Ca^{2+} conductance at presynaptic nerve fibers, with increased release of neurotransmitters, including acetylcholine [31, 32]. The clinical effects of this enhanced neural impulse

Table 2 Reports on scorpion envenomation by regions, study population, setting, and case fatality rates

First author; region; reference; years	Setting and sample size	Case fatality rate	Comment
Goyffon [5], Tunisia 1977	Hospital, a few were admitted; $n = 717$	0.35%	All fatalities <15 year old
Abroug [7], Tunisia 1994–1995	Hospital, controlled study $n = 825$; age > 10 year old	0.24%	Only 18% had systemic envenomation
Bouaziz [9], Tunisia 1990–2002	ICU, $n = 951$; 72% < 16 year old	7.5%	81% had severe envenomation
Ghalim [11], Morocco 1997	Prospective, hospitals $n = 275$;	Not reported	10% has systemic envenomation
Farghly [12], Egypt 1994–1995	Prospective, hospital $n = 302$; 78% < 18 year old	8%	19% with congestive heart failure
Mohamad [13], Egypt 2012	Retrospective, hospital: $n = 111$; <16 year	18%	53% had severe systemic envenomation
Amitai [14], Israel 1977–1982	Retrospective, hospital; $n = 51$; <13 year	3.9%	29% had severe systemic envenomation
Sofer [15], Israel; 1985–1992	Retrospective, historical control; 104 children in PICU, 52 with AV	1.9%	Treatment group 1985–9 controls in 1989–92 Time of AV $M = 1.56$ h after sting
el-Amin [17] Saudi Arabia; 1988–1994	Retrospective; hospitalized children; $n = 780$	Mortality reduced from 4.8% to 0%	Antivenom was very effective
Bosnak [20], Turkey 2004–2007	Retrospective hospitalized PICU; <15 years; $n = 45$	4.4%	All patients received antivenom and prazosin
Konca [22], Turkey 2015	Retrospective; hospitalized <17 years; $n = 80$	1.2%	57% with severe envenomation
Pipelzadeh [23], Iran 1993–1997	Retrospective, hospitalized $N = 354$; 40% < 10 years	8.4%	90% of the fatalities got antivenom >12 h after the sting. Most of severe cases due to <i>H. lepturus</i> .
Shahbazzadeh [24], Iran 2003	Retrospective; emergency departments; $n = 12,150$	0.02%	74.5% were mild
Dehghani [27], Iran 2001–2009	Review; retrospective $n = 42,500$	0.46%	

transmission include muscle fasciculations, respiratory, gastric, and pancreatic hypersecretion, and, occasionally, bradycardia [33, 34]. Parasympathetic stimulation also may cause vascular dilation of the penile arterioles supplying the corpus cavernosus, resulting in priapism.

Scorpion venom also induces sympathetic stimulation with excessive adrenergic discharge [35]. The clinical effects of scorpion envenomation may include parasympathetic and sympathetic stimulation. The nonspecific signs of tachycardia, tachypnea, hypothermia or hyperthermia, and leukocytosis are explained by

cytokine release (particularly, interleukin-6 [64] and interleukin-1) and increased autonomic neurotransmission. In a canine model, injection of venom from the yellow scorpion (*Leiurus quinquestriatus*) resulted in an early stage of increased cardiac output and hypertension, followed by a second stage of reduction in cardiac output [37]. These two stages may reflect an initial catecholamine discharge with a subsequent stage of catecholamine depletion. The mechanism of cardiotoxicity in scorpion envenomation is multifactorial, beginning with catecholamine overstimulation, causing hypertension and a

Fig. 2 Schematic representation of the voltage-gated channel in a neuron showing the site of scorpion toxin binding. The channel is roughly a $0.3 \text{ nm} \times 0.5 \text{ nm}$ rectangular hole formed by four of the transmembrane helices within this subunit (From Brody TM, Garrison JC: Sites of action: Receptors. In Brody TM, Larner J, Minneman KP (eds): Human Pharmacology: Molecular to Clinical, 3rd ed. St. Louis, Mosby, 1998, p 18. With permission)

transient phase of increased contractility. There is a diminished systolic performance in addition to the catecholamine effect. The combination of myocardial ischemia, excessive catecholamine effect, cardiac arrhythmia, and increased oxygen demand may result in acute myocardial infarction [38].

Respiratory failure, caused by pulmonary edema, is a common complication of severe scorpion envenomation. The pulmonary edema has a cardiogenic and noncardiogenic component. The latter is thought to occur as a result of increased vascular permeability induced by release of vasoactive substances [38]. Central nervous system involvement is more frequent in children with severe envenomation. In the case of *L. quinquestriatus* sting, central nervous system effects are explained partially on the basis of hypertension, causing hypertensive encephalopathy, and may respond to antihypertensive therapy (prazosin) [39]. Central nervous system manifestations, such as agitation, hyperthermia, hypertonus, seizures, and coma [14, 38, 40], also occur, however, in the presence of normal blood pressure, suggesting a more direct central mechanism of toxicity [38]. Intraventricular injection of extremely small doses of toxic *L. quinquestriatus* venom to rabbits (1/500 to 1/100 of the intravenous lethal dose) caused complex neurotoxicity with restlessness, tremors, and convulsions [38].

Clinical Manifestations

The severity of scorpion envenomation varies with the scorpion's species, age, and size, but clinical severity tends to be greater in children. As a general rule, venomous scorpions with thin claws are more toxic than scorpions with thick claws. Clinical severity ranges from local pain to encephalopathy and potentially fatal cardiotoxicity.

In most cases, adults stung by scorpions experience only local symptoms and signs consisting of pain, erythema, pruritus, edema, and paresthesias [34, 41], occasionally involving the extremities and the perioral area [41]. Local skin necrosis has been documented only from stings of *Hemiscorpius lepturus* in Iran and may occasionally be severe and accompanied by hemolysis and complicated by renal failure and disseminated intravascular coagulopathy [23, 29]. This is a unique and quite atypical form of scorpion envenoming, not seen following stings by other medically important scorpions, which can broadly be characterized as neuroexcitatory, as opposed to the dermonecrotic and hemolytic venom of *Hemiscorpius lepturus*.

For the numerous neuroexcitatory scorpion species, systemic envenoming reflects stimulation or depression of the central nervous system and stimulation of the sympathetic, parasympathetic, and

skeletal motor nervous systems. Skeletal motor and parasympathetic stimulation is manifest mainly as tongue and muscle fasciculation, gastric and pancreatic hypersecretion, and occasionally bradycardia [14, 33, 42]. Salivation, abdominal pain, nausea, and vomiting are common and may be attributed to stimulation of salivary glands and to pancreatitis [42]. Parasympathetic stimulation also may cause priapism, even in young boys [14, 43].

In the cardiovascular system, the increased sympathetic tone prevails, as reflected by the high incidence of tachycardia and hypertension (72% and 58%) and the much lower incidence of bradycardia and hypotension (14% and 5%) in victims of scorpion envenomation [34]. In a report of 386 children with scorpion stings from Saudi Arabia, tachycardia occurred in 32% of children and bradycardia in 0.77% [43].

Most scorpions with the potential to cause human envenomation in the Middle East and North Africa exert cardiotoxicity and neuroexcitatory neurotoxicity (see Table 1). A grading system for scorpion envenomation has been developed in Tunisia, consisting of three classes. This grading system has been further developed by a Consensus Group of experts in 2011, for the purpose of facilitating development of international clinical studies.

The three classes are: Class 1—local manifestations; Class 2—minor manifestations (non-life-threatening), and Class 3—severe manifestations (life-threatening) [44]. The details of this classification with the specific symptoms are specified in Table 3.

A simplified grading system, based on clinical grade and focused on treatment, has been published by Isbister and Bawaskar (Table 4), though presumably largely based on experience with scorpion sting in India [45].

Envenomation by the main venomous scorpion species in North Africa and the Middle East (*L. quinquestriatus* and *Androctonus crassicauda*) and India (*Hottentotta tamulus*) has a similar clinical course. Effects of mild envenomation are agitation, tachycardia, and sweating. In more severe cases, particularly in young children, additional symptoms include vomiting, abdominal

pain, salivation, dehydration, priapism, extreme agitation, generalized erythema, muscle rigidity and twitching, tremor, seizures, coma, pupillary changes (miosis, mydriasis, or anisocoria), hyperthermia, tachyarrhythmia or occasionally bradyarrhythmia and A-V Block, hypertension (less often hypotension), cardiac and respiratory failure, and death [14, 34, 43]. Idiopathic dilated cardiomyopathy was found to be eight times more frequent in patients with a past history of scorpion sting in India, despite apparent complete recovery from the acute envenomation [46].

Diagnosis and Laboratory Findings

The diagnosis of scorpion envenomation is made by the characteristic clinical presentation of the patient in an area in which scorpions are endemic. Occasionally the scorpion is seen, or the sting may be witnessed, though in nearly all cases the initial pain of the sting helps assure the diagnosis. The exception is dermonecrotic envenoming by *Hemiscorpius lepturus* in Iran and adjacent countries, where the sting may be initially painless and unnoticed, with later development of local skin damage and, in more severe cases, systemic envenoming characterized by intravascular hemolysis, DIC, shock, and sometimes multiorgan failure.

Laboratory abnormalities have been reported mainly from scorpion stings from the Middle East, North Africa, and India. Hyperglycemia and leukocytosis are nonspecific but common [14, 20, 47]. Cardiac ischemia is expressed by transient elevation of cardiac enzymes [38, 48] and electrocardiograms with depressed or elevated ST segment, Q waves in leads I and aVL, prolonged QT_c intervals, and peaked T waves [38]. Cardiac dysfunction is evidenced on echocardiography as diminished global wall motion with decreased systolic left ventricular performance and diminished ejection fraction [49–51]. Left ventricular dysfunction also has been shown by cardiac radionuclide scan [50]. Transient elevation of pancreatic enzymes has been reported [42]. For *Hemiscorpius lepturus* stings in Iran there may be laboratory evidence of hemolysis, coagulopathy, renal failure, and other secondary effects.

Table 3 Modified proposed classification of scorpion stings

Local manifestations	Minor manifestations (non-life-threatening)		Severe manifestations (life threatening) Presence of at least one of the following signs
Pain	Agitation/restlessness/excitement	Priapism	Cardiogenic failure
Local paresthesia	Altered mental status	Pupillary abnormalities	GCS score ≥ 6 (in absence of sedation)
Rash	Arthralgia	Rhinorrhea	Paralysis
	Ataxia	Salivation	Respiratory failure
	Dry mouth	Seizures	Paralysis
	Dystonia	Stridor	
	Fasciculation	Sweating	
	Gastrointestinal symptoms	Tachycardia	
	Generalized paresthesias	Temperature abnormalities	
	Hematuria	Urinary retention	
	Headache	Wheezing	
	Hypertension		
	Lacrimation		
	Muscular cramps		
	Myoclonia		
	Odynophagia		
	Pallor		
	Pancreatitis		

Modified from Khattabi et al. [44]

Treatment

Numerous treatments have been recommended for scorpion envenomation, including antivenom, prazosin, inotropic agents, atropine, vasodilators, and benzodiazepines (Table 4). However, the evidence for the effectiveness of most treatments is variable, and types of treatment appear to vary according to region [45].

As a general approach, the following recommendations can be made:

First aid and prehospital treatment:

1. Cleansing the sting site with alcohol or soap.
2. Reducing the spread of the venom before arriving at a medical facility is crucial. Several reports emphasize the critical effect on the outcome of delay in time of arrival of the victim to medical facilities [11, 15, 38]. This is explained by the rapid spread of the venom [52]. To reduce

lymphatic spread of the venom, immobilize the stung limb (Grade III recommendation).

3. Application of an elastic bandage or gauze bandage with light pressure on the sting site may reduce the spread of the venom. This “pressure-immobilization technique” is endorsed by the National Health and Medical Research Council of Australia to reduce lymphatic spread in toxic snake bites [53]. It is logical to also use such technique for venomous scorpions. Increased venom concentration at the sting site should not be a problem in envenomation by most scorpion species as local necrosis is rare with scorpion stings by most scorpion species. Applying this technique is not recommended in stings by *Hemiscorpius lepturus* in Iran and Iraq, which tends to cause local necrosis [23, 29]. Application of tourniquet, cauterization, or incision and drainage are contraindicated for all scorpion stings. An Australian study of

Table 4 Clinical grade and treatment of scorpion stings

Grade	Effects	Treatment
1	Local effects only	Analgesia, local anesthesia
2	Autonomic excitation	Antivenom, prazosin
	Agitation and anxiety	Benzodiazepines
3	Pulmonary edema	Admission to intensive care unit, noninvasive or mechanical ventilation, antivenom
	Hypotension and cardiogenic shock	Antivenom, dobutamine
	Severe neuromuscular excitation (associated with <i>Centruroides</i> species)	Antivenom, benzodiazepines
4	Multiorgan failure, including coma, seizures, and end-organ damage caused by hypotension	Supportive care, mechanical ventilation, inotropes (e.g., dobutamine), benzodiazepines

Adapted from Isbister and Bawaskar [45]

venomous snake bites without local necrosis in a rat model showed that local application of nifedipine, lidocaine, and NO releasing ointments markedly reduced the spread of venom from the sting site [53]. However, there are no published data for such treatments in humans.

4. Transport the victim to a medical facility as soon as possible, particularly when the victim is an infant or small child. If it is known or suspected that the scorpion is capable of envenoming humans, all victims of sting should be transported to a hospital or clinic.
5. When an elastic bandage has been applied, it should be removed under observation when the victim has arrived at a medical facility.
6. Analgesics (acetaminophen, ibuprofen) are recommended for pain relief [45]. Topical application of lidocaine may also be helpful.
7. In most cases, adults stung by scorpions do not develop a systemic envenomation syndrome. Close observation outside of a health care facility for 2–6 h is sufficient in these cases. In

regions where cardiotoxic scorpions are endemic (see Table 1), an electrocardiogram should be performed.

Hospital admission and in-hospital treatment:

1. A clinical score predicting the need for hospitalization in scorpion envenomation was developed by Nouria et al., from Tunisia, based on a prospective study in 868 patients with scorpion envenomation with a validation group of 435 patients. The following variables were strong predictors for admission: priapism, vomiting, hypertension (>160 mmHg), administration of corticosteroids before arrival to emergency department, delay (>30 min) to emergency department arrival, hyperthermia, and tachycardia [8].
2. In cases of systemic envenomation, the principles of management are observation, cardiac monitoring, supportive treatment with intravenous fluids and electrolytes, sedatives and analgesics, and cautious use of cardiovascular agents, including vasodilators, adrenergic antagonists, or calcium channel blockers, in the hypertensive phase. Sofer and colleagues [15] advocated the use of hydralazine or nifedipine. Bawaskar and Bawaskar [36] found prazosin to be safer and more effective than nifedipine in their patients stung by the Indian scorpion, *Hottentotta tamulus* and recommended using prazosin alone in patients with hypertension and tachycardia from scorpion sting. In a controlled study, these authors reported lower complication rates (no fatalities) in patients treated with prazosin compared with patients treated with nifedipine or supportive care alone (fatality rates of 35% and 25%, respectively). However, subsequent studies by these authors have indicated that antivenom is the most effective treatment.
3. Elatrous and coworkers from Tunisia reported the efficacy of dobutamine infusion at 7–20 µg/kg/min in 19 patients with severe scorpion envenomation and acute pulmonary edema, of whom ten also had severe hypotension. In these patients, cardiac output, blood pressure, tissue oxygenation, and clinical outcome improved

significantly, but there were two fatalities [54]. Antiarrhythmics, such as lidocaine, may be required [38]. In an experimental envenomation by *L. quinquestriatus* in rabbits, lidocaine infusion significantly attenuated venom-invoked effects and reduced mortality [55].

Use of sedatives to reduce anxiety and agitation has an important role in the treatment of symptomatic patients. Benzodiazepines are used for sedation [45]. At the Hadassah University Hospital, Mt. Scopus, Jerusalem, we have used diazepam or midazolam at doses titrated to control agitation and anxiety in children with scorpion envenomation with good response. Steroids have no role in the treatment of scorpion envenomation [56].

Antivenom Therapy

Specific antivenom therapy has been used for several decades. Most antivenom preparations consist of animal serum (mainly equine) and are immunoglobulin F(ab)₂ fragments. The types of scorpion antivenom used in each country were summarized by Bahloul et al. in 2013 [47]. Those relevant to Middle Eastern and North African appear in Table 5.

The antivenom currently used in Israel is SCORPIFAV, a polyvalent scorpion antivenom against *A. australis*, *B. occitanus*, and *L. quinquestriatus*, produced by Sanofi-Pasteur (France).

Numerous reports exist on the clinical use of specific antivenom preparations from Middle Eastern and North African countries [7, 11, 15–17, 38, 43, 57].

Due to ethical limitations, most studies are retrospective, observational, or historical controls. There are only a few prospective, randomized, controlled studies [6, 7]. Reports on antivenom therapy are summarized in Table 6. Of the seven reports summarized there, five concluded that antivenom is effective [11, 16, 17, 38, 57], two concluded that antivenom is not effective [7, 15], and one gave data only on safety and did not report efficacy [43]. The two studies reporting a

Table 5 The types of scorpion antivenom used in Middle Eastern and North African countries (Adapted from Bahloul et al. [47])

Antivenom	Species	Country
Polyvalent scorpion antivenom	<i>Androctonus australis garzonii</i> , <i>B. occitanus tunetanus</i> , and <i>Tityus serrulatus</i>	Morocco
Purified polyvalent anti-scorpion serum (equine)	<i>Leiurus quinquestriatus</i> <i>Androctonus amoreuxi</i> <i>Androctonus crassicauda</i> <i>Androctonus aeneas</i> <i>Androctonus australis</i> <i>Scorpio marus palmatus</i> <i>Buthus occitanus</i>	Egypt
Scorpion antivenom (Pasteur Institute of Algeria)	<i>Androctonus australis</i>	Algeria
Bivalent scorpion antivenom (Institut Pasteur, Tunis, Tunisia)	<i>A. australis</i> and <i>B. occitanus</i>	Tunisia
Polyvalent scorpion antivenom	<i>Leiurus quinquestriatus</i> , <i>Androctonus crassicauda</i> , <i>Buthus arenicola</i> , <i>Butus mimax</i> , <i>Buthus occitanus</i> , <i>Leiurus quinquestriatus hebreus</i> , and <i>A. amoreuxi</i>	Saudi Arabia
Monovalent scorpion antivenom	<i>Leiurus quinquestriatus</i>	Israel

lack of antivenom efficacy were controlled, and one was randomized controlled. However, the main limitation was that 82% of the patients had only local signs of envenomation (grade 1) and only 1% of patients in both groups had life-threatening envenomation [7, 57]. A meta-analysis of controlled studies by Abroug et al. concluded that antivenom for scorpion envenomation is ineffective [58]. However, the main weight of randomized controlled studies in this study was given to the original study of these authors, which had the largest number of patients

Table 6 Published studies on antivenom efficacy in scorpion envenomation in the Middle East and North Africa

Study; region; years; scorpion species	Study design; sample size	Antivenom type; dose; and route	Results and conclusion	Comment
Sofer et al. [15]; Israel; 1985–1992; <i>Leiurus quinquestriatus</i>	Retrospective, historical control; 104 children in PICU, 52 with AV	Specific AV, donkey's serum; 5–15 mL; IV	No effect; emphasis on supportive therapy	Treatment group in 1985–9; Controls in 1989–92 Time of AV $M = 1.56$ h after sting
Ismail [16, 38]; Saudi Arabia; 1991–1992; <i>Androctonus</i> , <i>Leiurus quinquestriatus</i>	Statewide, multicenter; 24,000 patients	Specific AV; ≥ 5 mL; IV	Mortality reduced from 4–6.8% to $<0.05\%$	Efficacy requires prompt IV infusion and large dose
el-Amin et al. [17]; Saudi Arabia; 1988–1994; <i>Leiurus quinquestriatus</i> , <i>Androctonus</i>	780 hospitalized children and children treated as outpatients	Specific AV; ≥ 5 mL; IV	Mortality reduced from 4.8% to 0%	Very effective
Gajre and Dammas [43]; Saudi Arabia; 1991–1995; <i>Leiurus quinquestriatus</i> , <i>Androctonus</i>	182 children treated, 90% symptomatic	Specific AV; 5 mL (10–20 mL for severe patients); IV	Efficacy not reported; adverse reactions in 13.7%, severe in 1%	Restrict AV use to patients with systemic envenomation
Abroug et al. [7]; Tunisia; 1994–1995; <i>Androctonus australis</i> , <i>Buthus occitanus</i>	Randomized, controlled; 825 patients >10 year old, 412 treated	Specific bivalent AV; 20 mL; IV	No effect; four (1%) developed anaphylactic reversible shock	The antivenom was not highly specific [57] 82% of patients had only local signs and only 1% of patients had life-threatening envenomation
Krifi et al. [6]; Tunisia; 1993–1997; <i>Androctonus australis</i> , <i>Buthus occitanus</i>	Randomized, controlled; 147 severely envenomed children, 1–2 doses IV or IM or no AV	Specific bivalent AV, Pasteur Institute, Tunisia; 5–30 mL; IV	AV given IV – effective; IM – not effective	
Ghalim et al. [11]; Morocco; 1997; <i>Androctonus mauretanicus</i> , <i>Buthus occitanus</i>	Retrospective; 275 patients	Specific bivalent AV, Pasteur Institute, Tunisia; 2–10 mL; IV ^a	Effective	Prompt use and large dose important

AV antivenom, PICU pediatric intensive care unit

^aSome patients received 2–5 mL of antivenom, and some received 1 mL. In those who received the higher dose, there was a higher degree of circulating venom depth

[7] and affected the overall result. In a recent review of scorpion envenomation by Isbister and Bawaskar, the authors conclude: “Although the evidence in favor of antivenom is heterogeneous, given the small sample size of the trials with positive results and the different scorpion species across studies, the reports, when taken together, suggest that administration of antivenom after a sting is of some benefit” [45].

Of note, antivenom for the scorpion *Centruroides sculpturatus* from Southern United States and for the Indian scorpion *Hottentotta tamalus* were shown to be effective in randomized controlled studies [45] (Grade I evidence).

Ismail [16, 38] from Saudi Arabia reported robust data on 24,000 patients with scorpion envenomation treated by a national protocol. Thousands of these patients were treated with

antivenom, with a reduction in the fatality rate from 4% to 6.8% to less than 0.05%. Among 780 children, the use of antivenom therapy resulted in reduction of mortality from 4.8% to 0% [17].

In Iran, there are trials to prepare a specific antivenom for envenomation by the scorpion *Hemiscorpius lepturus*, which so far were successful only in an animal model [59]. However, this antivenom is currently used in clinical practice in Iran.

Important points regarding the optimal use of antivenom can be inferred from these reports, as follows:

1. Because of regional variations in scorpion species and specific antivenom preparations, *always obtain the advice of local experts* (i.e., poison information centers, medical toxicologists, or treatment centers with expertise in the field of scorpion envenomation).
2. Reserve antivenom preparations for patients with systemic toxicity. A suggested guideline for treatment with antivenom is the appearance of two or more of the signs and symptoms of systemic envenomation listed in the box below or the occurrence of one of the following: arrhythmia, hypertension, hypotension, seizures, coma, and pulmonary edema (Grade II-2 evidence).
3. When indicated, give antivenom promptly after onset of systemic signs or symptoms. In the event of a rash appearing during antivenom administration, decrease the infusion rate, add intravenous antihistamine, and continue the antivenom infusion, with caution and standby intravenous epinephrine and airway management equipment.
4. Administer antivenom *intravenously only*. The intramuscular route is not effective, likely due to the slow absorption and distribution of the large antibody molecules from the intramuscular injection site [6].
5. The volume required depends on the preparation and the initial and subsequent responses to treatment but may vary from 6 to 10 mL in severe cases. Always consult with local experts about the proper preparation, dose, and precise instructions about how to administer the antivenom. The antivenom is diluted in 50 mL of normal saline and administered intravenously starting with a slow infusion rate and increasing gradually. Skin testing generally is not performed because when antivenom is deemed necessary, there should not be a further delay in its administration and there is no evidence indicating reliability of such testing but ample evidence of the potential hazard. The safety of specific scorpion antivenom (i.e., low likelihood of anaphylactic or anaphylactoid reaction) given in various geographic locations is considered to be generally satisfactory [14, 38]. This safety is related to the low protein content of the antivenom. Paradoxically, the theoretical likelihood of patients with severe envenomation developing an anaphylactoid reaction is lower than that of patients with mild envenomation because severe venom toxicity causes the release of massive amounts of catecholamines, inhibiting mast cell degranulation [60].
6. The dose should not vary with the age or weight of the patient because it should be directed at neutralizing a given amount of venom introduced by the scorpion into the patient's body. At the Hadassah Hospitals, we have used antivenom therapy to treat more than 50 children with systemic scorpion envenomation. In many instances, an impressive reversal of signs and symptoms was observed immediately after antivenom administration. This specific antivenom is the only one available in Israel; however, it has been reported also to be effective in the case of envenomation by another (nonhomologous) scorpion species, *A. crassicauda* [61]. The explanation of this effect is related to the similarity in venom composition between these two scorpion species.
7. Patients who receive antivenom should be followed at home for the next few days. If serum sickness occurs, antihistamines or a short course of oral steroids should be given according to the severity of symptoms [62].
8. Advances in supportive care and antivenom therapy have markedly improved the outcome of patients treated for scorpion envenomation.

Indications for ICU Admission in Neuroexcitatory Scorpion Envenomation

Infants and young children (<5 years old)

Anyone with systemic manifestations consisting of two or more of the following:

Cardiovascular: tachycardia/bradycardia, hypertension/hypotension, arrhythmia

Neurologic: agitation, lethargy, coma, tremor, hypertonicity, seizures, opisthoclonus, paresthesia (other than at the sting site)

Respiratory: tachypnea, respiratory distress, stridor, pulmonary edema

Dermatologic: sweating, flushed skin, “goose bumps”

Laboratory: electrocardiogram abnormalities, elevated myocardial enzymes, echocardiogram evidence of cardiac wall dysfunction (reduced contraction)

One of the following: arrhythmia, hypertension (new onset), hypotension, seizures, lethargy, coma, pulmonary edema, electrocardiogram or echocardiogram abnormalities, increased myocardial enzymes – CKMB, troponin

Criteria for ICU Discharge in Neuroexcitatory Scorpion Envenomation

Infants and young children (<5 years old) – lack of signs or symptoms of systemic envenomation for 6 h and normal electrocardiogram

Others – resolution of systemic manifestations of scorpion envenomation for 3 h and no new abnormalities on electrocardiogram

particularly compared to significant systemic envenoming, therefore pregnancy should not be considered a contraindication for antivenom treatment. As for poisoning by other toxins, indications for treatment should be guided by maternal clinical state.

Key Points in Scorpion Envenomation

1. Venomous scorpions exist in different regions, usually in warm climates, and are active in the warm season, particularly after dark.
2. Because of marked geographic variations in scorpion species and their toxicity, the clinician *always* must consult with local experts about treatment and administration of antivenom.
3. As a rule, venomous scorpions with thin claws are more toxic than scorpions with thick claws.
4. Young children are at greater risk for severe envenomation after a sting.
5. When antivenom is indicated, the dose should be similar in children and adults.
6. After being stung, it is helpful if the patient can catch or take a photo of the scorpion, for identification.
7. In contrast to bee stings, scorpions excrete only a small fraction of their venom in one sting and could cause severe toxicity immediately in repetitive stings [63].
8. After being stung, the patient should not run. Immobilization of the affected limb is important to slow venom distribution.
9. Incision and drainage at the site of the sting is contraindicated.

Special Populations

Pregnant Patients

Data are insufficient to make conclusions about the safety of antivenom administration in pregnant women. However, in general there is no evidence antivenom is harmful in pregnancy,

Introduction

Scorpions are arthropods with a hard exoskeleton and eight legs. Cephalad to the body are two large pinchers, which the scorpion uses to grasp prey. Caudal to the body is the tail, which terminates in the telson. This last segment contains both a venom gland and a stinger (Fig. 1).

While there are hundreds of different species of scorpions, only a few are capable of causing clinically significant envenomations in humans. Most of the dangerous scorpions worldwide belong to the Buthidae family, which includes the genera *Leiurus* (the Middle East), *Buthus* and *Androctonus* (North Africa), *Mesobuthus* (Asia, especially India), and *Tityus* (South America). The genus *Centruroides* is found in parts of North and Central America [1]. In the United States, the only native scorpion capable of producing a severe or life-threatening envenomation is the bark scorpion (*Centruroides sculpturatus*), which was previously referred to as *C. exilicauda*, although more recent data suggests these are, in fact, two different species [2]. *Centruroides sculpturatus* is found almost exclusively in the American southwest and parts of Mexico. In the United States, it is mostly concentrated in Arizona, although the bark scorpion is also found in New Mexico and parts of Nevada, Texas, and California [3, 4]. Rarely, such scorpions have “hitchhiked” on airplanes, resulting in envenomations outside of their normal geographical distribution [5].

Fig. 1 Bark scorpion, *Centruroides sculpturatus* (*exilicauda*). (a) Enlarged chela. (b) Enlarged vesicle showing a tubercle below the stinger. The body length including telson is 55 mm (From Ref. [37])

Fig. 2 Bark scorpion showing its long pedipalps and its unique tail

The bark scorpion is a small (mean length 6.5 cm with a range of 1–7 cm), tan/brown, nocturnal, non-burrowing animal which is capable of climbing vertically [3, 6, 7]. These animals reside both in rural and urban dwellings [7]. They prey on small lizards, insects, and arachnids. *Centruroides sculpturatus* can be distinguished from other scorpion species by its long pedipalps and its unique tail, whose terminal segment is rectangular, rather than square (Fig. 2).

While other species of *Centruroides* (e.g., *C. hentzi*, *C. gracilis*, *C. guanensis*, *C. vittatus*) and other genera (e.g., *Hadrurus* or *Vaejovis*) are present in the United States, stings by these scorpions are of little medical importance and rarely cause symptoms other than localized pain. Consequently, the rest of this chapter will focus exclusively on *C. sculpturatus*.

Historically, mortality following envenomations from *C. sculpturatus* was not uncommon.

Fig. 3 Schematic representation of the voltage-gated channel in a neuron showing the site of scorpion toxin binding. The channel is roughly a $0.3 \text{ nm} \times 0.5 \text{ nm}$ rectangular hole formed by four of the transmembrane helices within this subunit (From Ref. [38])

In the 1930s there were 40 deaths directly attributed to stings from the bark scorpion [8]. Deaths today, however, remain relatively rare. Despite accounting for more than 19,000 calls annually to US poison control centers, there were no reported fatalities in 2012 and only a single reported fatality in 2013. The declining mortality is largely attributed to both improved access to healthcare and improvements in supportive care [9].

The majority of envenomations occur in adults and require little intervention [4, 10]. Despite accounting for a smaller percentage of envenomated patients, pediatric patients are much more likely to become significantly ill and require critical care management [4].

Biochemistry and Clinical Pharmacology

Scorpion venom is a complex mixture of low molecular weight proteins, oligopeptidases, nucleotidases, lipids, mucoproteins, and amino acids [2, 11]. Among the various *Centruroides* species, there is a high degree of homology in the peptide sequence among the various toxins [12–14]. Mouse models demonstrate toxicity beginning at 1.12 mg/kg, with lethality consistently occurring at doses exceeding 3 mg/kg [2, 8]. Additional rodent studies have demonstrated

reduced time intervals between envenomation and mortality with subsequent envenomations. However, this time difference was not associated with changes in serum levels of antivenom antibodies [15].

Toxicokinetic studies have been performed utilizing the venom from *C. limpidus*, a scorpion indigenous to Mexico. Following subcutaneous injections in a rabbit model, the venom is distributed in a two-compartment model. The volume of distribution was 850 ml/kg, with the maximal plasma concentration occurring approximately 1 h postinjection. The toxic fraction of the venom had an α elimination half-life of 0.35 h and a terminal elimination half-life of 1.9 h [16]. Despite the relatively short half-life in animals, limited human data with *C. sculpturatus* venom indicates patients may remain symptomatic with detectable levels for at least 20 h post envenomation [17]. The venom is primarily renally eliminated.

Pathophysiology of Toxic Effects

In general, scorpion venom targets voltage-gated sodium or potassium channels [11, 18] (Figs. 3 and 4). *Centruroides sculpturatus* venom has been shown to inhibit ERG potassium channels [12, 19] and prevent inactivation of the voltage-gated sodium channels [20–24] (Fig. 5).

Fig. 4 β -scorpion toxins promote Nav channel opening. The β -scorpion toxin CssIV is found in the venom of the *Centruroides suffusus suffusus* scorpion (silhouette on the left), and amino acids important to toxin functionality have been identified in both the hydrophobic region and a ring of charged residues a (middle figure: protein backbone of the related β -scorpion toxin TsVII is shown together with the

electrostatic surface of the protein). At 1 μ M, CssIV opens rNav1.2a at voltages where the channel is normally closed. Current trace shown was evoked from a holding potential of -90 mV to a voltage of -40 mV when expressed in *Xenopus oocytes*. Black is control and red is after addition of 1 μ M CssIV (right) (From Ref. [39])

Fig. 5 α -scorpion toxins hamper Nav channel fast inactivation. The α -scorpion toxin AaHII is produced by the *Androctonus australis* Hector scorpion (silhouette on the left), and amino acids important to toxin functionality have been identified in both the hydrophobic patch as well as charged residues surrounding it (middle figure: protein

backbone is shown together with the electrostatic surface of the protein). At 100 nM, AaHII inhibits fast inactivation of rNav1.2a currents evoked from a holding potential of -90 mV to a voltage of -20 mV when expressed in *Xenopus oocytes*. Black is control and red is after addition of 100 nM AaHII (right) (From Ref. [39])

Consequently, there is an increase in neuronal sodium influx, resulting in prolonged duration and amplitude of the action potential. A study examining the effects of the venom of various species of *Centruroides*, although not specifically *C. sculpturatus*, demonstrated reduced sodium conductance, left shift in the voltage-dependent activation and induction or resurgent currents at negative voltages [25].

Clinical Presentation and Life-Threatening Complications

The most severe envenomations occur in young children, although high-grade envenomations occur in all ages [4]. Following an envenomation, symptoms generally develop within minutes to an hour and may progress rapidly [9, 10]. The clinical effects of scorpion envenomation form the

Table 1 Grading system for envenomations by *C. sculpturatus* (Adapted from Ref. [4])

Grade	Symptom
I	Local pain or paresthesias
II	Pain or paresthesias distal to the bite site
III	Either isolated cranial nerve dysfunction or diffuse somatic skeletal neuromuscular dysfunction
IV	Both cranial nerve dysfunction and somatic skeletal neuromuscular dysfunction

basis for our current grading system, which is shown in Table 1.

Most patients develop only minimal symptoms and are thereby classified as having a grade I or II envenomation. These symptoms include pain or paresthesias either at the sting site (grade I) or more diffusely throughout the envenomated extremity and body (grade II).

Most children with high-grade envenomations experience autonomic hyperactivity, including tachycardia, hypertension, and/or fever [9, 26]. Vomiting is relatively common, especially at the onset of toxicity [9]. Respiratory distress, including hypoxemia or stridor, is also frequently observed. The respiratory findings may result from the combination of asynchrony of the respiratory musculature, loss of tongue control, and increased salivation. This may be compounded by the respiratory depressant effects of opioid analgesics, especially with concurrent administration of benzodiazepines. Respiratory findings occur in approximately one-third of patients with severe envenomation [9, 10].

The presence of cranial nerve or neuromuscular dysfunction defines a high-grade (grade ≥ 3) envenomation. Cranial nerve findings can include opsoclonus, disconjugate gaze, hypersalivation, tongue fasciculations, slurred speech, and occasionally stridor. The somatic skeletal neuromuscular findings can include myoclonic jerking movements of the extremities, arching and twisting of the torso, general restlessness, agitation, and tremor. While the myoclonic jerks may resemble seizure-like activity, they are typically asymmetric, the patient is awake and alert, and epileptic findings are not present on EEG.

Cutaneous findings are notably absent from stings by *C. sculpturatus*, although a positive tap test, performed by tapping the examiner’s fingers over the sting site to elicit an increase in pain, may be noted. In addition, unlike other species of scorpions, direct cardiotoxicity is not expected following envenomation by *C. sculpturatus*.

Diagnosis

The diagnosis of bark scorpion envenomation is largely based on history and physical examination. Young children are often unable to provide the history of a sting, so details regarding the onset of effects (i.e., sudden inconsolable agitation in a previously well child) and recognition of characteristic clinical findings must be relied upon in diagnosing envenomation [27]. Because scorpions are nocturnal, patients may be awakened by the onset of symptoms. Cutaneous findings are usually absent. A positive tap test may help aid in the presumptive diagnosis; however in young children with severe agitation, it can be difficult to identify a positive response. While serum venom concentrations can be obtained [17], their use is limited to research settings and is not routinely available. Thus, the diagnosis remains clinical.

The differential diagnosis of scorpion envenomation includes both toxicologic (e.g., methamphetamine toxicity, black widow envenomation) [28, 29] and non-toxicologic etiologies (e.g., thyrotoxicosis, central nervous system infection).

Treatment

One of the primary reasons for the reduced mortality seen today is improved access to care, with supportive care being paramount [9].

Following envenomation, patients should be observed for progression of clinical effects. However, most patients with mild symptoms can be managed at home without referral to a medical facility [4, 10, 30, 31] (grade III recommendation).

Patients with a compromised airway, or those with ineffective ventilatory effort, should be intubated as per standard indications (grade III recommendation).

Patients with significant hypersalivation are sometimes treated with small doses of atropine; however, there is not sufficient evidence supporting this practice to recommend its routine use [9, 26, 32] (grade III evidence). Analgesics should be administered to those with significant pain (grade III recommendation). Most patients who have high-grade envenomations, and are thus unable to communicate verbally, should be assumed to have pain and can be treated with analgesics empirically. Due to its lack of significant histaminergic effects, fentanyl is the preferred analgesic [3] and should be administered with a starting dose of 1 mcg/kg intravenously (grade III recommendations). Additional doses can be titrated based on need. In addition to analgesics, benzodiazepines should be administered to assist in the control of neuromuscular excitation and agitation [9, 10] (grade III recommendation).

In August, 2011 the United States Food and Drug Administration approved *Centruroides* (scorpion) immune F(ab')₂ antivenom for the treatment of scorpion envenomation. While the approval is not based on grade of envenomation, because low-grade envenomations universally do well without therapy, and the expensive nature of the antivenom, its use is primarily reserved for those with grade III or IV envenomation. The use of this antivenom has been demonstrated to be highly safe and effective [33–35] (grade Ib evidence). The use of this antivenom in an emergency department may obviate the need for admission and/or transfer to a pediatric facility for admission [35]. The cost of such therapy can exceed \$10,000, and some data suggests its use may not be a cost-effective option [36]. If antivenom is not an option for patients with high-grade envenomations, admission to an intensive care unit, and possible mechanical ventilation, is indicated. During the approximately 2-year period between September 2004 through July 2006 when antivenom was not available in Arizona, nearly 25% of all grade III or IV scorpion envenomations required intubation with ventilatory support [9].

While antivenom is an option for patients with high-grade envenomations, supportive care is paramount. Antivenom should be considered an adjunctive agent for severe envenomations, but its use is not necessarily the standard.

Indications for ICU Admission

Grade III or IV envenomations not treated with antivenom

Hypoxia that does not resolve after antivenom administration, especially if concern for significant aspiration

Mechanical ventilation

Key Points

- Most patients will develop only minor symptoms and not require admission.
- Antivenom may be administered for high-grade symptoms.
- Clinicians should prepare for possible respiratory compromise and treat any impending respiratory failure with endotracheal intubation.

Criteria for ICU Discharge

- Resolution of significant respiratory compromise
- Resolution of symptoms

Venomous snakes are undoubtedly the most significant cause of both major morbidity and mortality among all terrestrial venomous and poisonous animals. Although poisoning by marine animals may affect large numbers of people, mortality is comparatively rare, and thus venomous snakes are the leading cause of death from venomous and poisonous animals in all environments. In some parts of the rural tropics, snakebite is in the top 10–15 most important health problems, but in temperate “Western” countries, snakebite is often considered to be of negligible significance, a designation not necessarily in tune with reality.

Types of Venomous Snakes

Even though there are approximately 3000 species of snakes globally, only about 600 species are clearly venomous. The higher-level taxonomy of snakes has undergone significant change in recent years and the previous view that all of them are found in just four snake families: Colubridae, Elapidae (includes sea snakes, subfamily Hydrophiinae), Atractaspididae, and Viperidae is no longer valid. The current taxonomy places venomous snakes in families Colubridae, Natricidae, Elapidae, Lamprophiidae, and Viperidae (Table 1) [1].

Table 1 Current taxonomy of higher-level snakes, including all clearly venomous taxa. *NFFC* non-front-fanged venomous, *FFV* front-fanged venomous. Note all these snakes are classed as Colubroid, but the precise subclassification into several superfamilies remains contentious [1]

Superfamily	Family and subfamily	Relevant examples of included genera	Type of venomous snakes
Superfamily Colubroidea	Colubridae		
	Colubrinae	<i>Boiga, Dispholidus, Thelotornis</i> , etc.	NFFC
	Grayiinae		
	Calamariinae		
	Dipsadidae		
	Dipsadinae	<i>Leptodora, Sibynomorphus</i> , etc.	NFFC
	Heterodontinae	<i>Heterodon</i>	NFFC
	Xenodontinae	<i>Alsophis, Boiruna, Clelia, Hydrodynastes, Phalotris, Philodryas, Tachymenis</i> , etc.	
	Natricidae	<i>Natrix, Rhabdophis, Thamnophis</i> , etc.	NFFC
	Pseudoxenodontidae		
Superfamily Elapoidea	Elapidae	(Includes sea snakes, e.g., “Hydrophiinae”)	FFV
	Lamprophiidae		
	Atraspinae		FFV
	Lamprophiinae		
	Psammophiinae		
	Pseudoxyrhophiinae		
Superfamily Homalopsoidea	Homolopsidae	<i>Cerberus, Homalopsis</i> , etc.	
Superfamily Viperoidae	Viperidae		FFV
	Azemiopinae		
	Crotalinae		
	Viperinae		

Among those snakes considered venomous, there are two morphologic subgroups, based on the fang and toxin-producing gland. These subgroups do not precisely relate to taxonomic classification. Classic venomous snakes such as cobra-type snakes (family Elapidae) and vipers, including pit vipers (e.g., rattlesnakes, etc.) (family Viperidae), have fangs placed toward the front of the mouth (FFV). Other snakes considered as venomous either have fangs further back in the mouth (sometimes labeled as “back fanged”) or no clear fangs; this group are labeled as “non-front-fanged colubroids” (NFFC).

To add a further layer of complexity, there is an ongoing debate about what constitutes venomousness, with some toxinologists advocating a much broader definition that sees almost all snakes, many lizards, and other vertebrates as “venomous” (the Toxicofera hypothesis), a view rejected by others, including this author, and by the vast majority of toxinologists at a formal debate on this hypothesis held at Oxford University as part of the World Congress of the International Society on Toxinology, September 2015. The various hypotheses and definitions of venom and venomousness have recently been reviewed [2].

Medically Important Nonvenomous Snakes

When compared with the human toll from venomous species, nonvenomous snakes cause few problems, but it should not be forgotten that a few large nonvenomous species, notably the pythons

and boas (family Boidae), can cause significant bites and rarely may kill and more rarely still may eat humans.

Pythons and boas have many long, sharp, recurved teeth (Fig. 1) capable of penetrating deeply, even to bone in some areas such as the hand. These teeth, in addition to causing mechanical injury, may be expected to be coated with bacteria and thus may cause significant local infection. Besides the effects of the bite, large pythons and boas can potentially wrap around a human torso or neck and cause crush injuries. Such injuries may include significant internal organ damage in addition to the lethal effects of constriction of the cardiovascular and respiratory systems.

Some researchers have claimed that even the python/boa group can produce toxins from oral glands, thus are technically venomous. This view is controversial and, in practical terms for bites to humans, irrelevant, as there is no evidence indicating that bites by these snakes cause envenoming in humans [2].

NFFC Snakes

In the past most snakes were generally considered nonvenomous and distributed globally in a single family, Colubridae (Fig. 2). As noted earlier, a revised taxonomy has split this family into many distinct families and subfamilies (Table 1), and among these, a number of families and subfamilies contain at least some species considered as venomous [1]. These latter snakes, designated NFFC (see earlier), do not have fangs at the

Fig. 1 Boid skull showing large array of long, sharp recurved teeth (Copyright © Dr. Julian White)

Fig. 2 Approximate global distribution of “colubrid” snakes, covering the following families: Colubridae, Dipsadidae, Natricidae, Pseudoxenodontidae,

Lamprophiidae (but excluding Atractaspinae), Homolopsidae (Copyright © Dr. Julian White)

Fig. 3 Diagrammatic representation of a typical colubrid snake head and fang position (Copyright © Dr. Julian White)

front of the mouth, and some have no discernable fangs at all. Venom is generally produced in a low-pressure elongated gland, Duvernoy’s gland, but not all snakes possessing Duvernoy’s gland are necessarily “venomous.” However, a few of these species have evolved fangs toward the back of the mouth (Fig. 3) that deliver venom. Several

of these species have caused human fatalities or major envenoming (Table 2). A further group of NFFC snakes have evolved toxic oral secretions that are inoculated during the biting process, though not with fangs. There is increasing evidence that at least some of these species can cause significant injury to humans [1]. Some other NFFC snakes reported to cause effects in humans are listed in Table 3. This list is not exhaustive, and most NFFC snakes should be considered to have some potential of causing at least local envenoming, whether via fangs or inoculation of toxic oral secretions.

Family Elapidae

It is a large and diverse family of exclusively venomous snakes covering all continents (except Antarctica) and several major oceans (Fig. 4), these snakes have well-developed fangs toward the front of the mouth that can deliver often highly potent venom produced in paired venom glands (Fig. 5) [1, 4]. The archetypic elapid snake is the Indian cobra, but the typical cobra hood is present

Table 2 NFFC snakes reported to have caused major or lethal envenoming [1]

Scientific name	Common name	Effect
<i>Dispholidus typus</i>	Boomslang	Coagulopathy and hemorrhage
<i>Thelotornis</i> spp.	Vine snakes	Coagulopathy and hemorrhage
<i>Rhabdophis</i> spp.	Yamakagashi, red-necked keelback	Coagulopathy and hemorrhage
<i>Balanophis ceylonensis</i>	Sri Lankan keelback	Local swelling ± discoloration, bleeding, lymphangitis; coagulopathy and hemorrhage reported in single case [3]
<i>Malpolon monspessulanus</i>	Montpelier snake	Mild neurotoxicity (poorly defined)
<i>Philodryas olfersii</i>		
<i>Boiga irregularis</i>	Brown tree snake	Local swelling plus respiratory distress and possible mild paralysis in infants only

Table 3 Some NFFC snakes reported capable of causing mild envenoming^a [1]

Scientific name	Common name	Effect
<i>Ahaetulla nasuta</i>	Asian green whipsnake	Local swelling ± discoloration, lymphangitis
<i>Amplorhinus multimaculatus</i>	African many-spotted snake	Local swelling ± headache, nausea
<i>Boiga</i> spp. (e.g., <i>blandingii</i> , <i>ceylonensis</i> , <i>dendrophila</i> , <i>forsteni</i>)	Tree snakes from Africa and Asia	Local swelling ± discoloration, bleeding, lymphangitis, headache, nausea
<i>Cerberus rynchops</i>	Indian dog-faced water snake	Local swelling ± discoloration, lymphangitis
<i>Coluber</i> spp. (e.g., <i>ravergieri</i> , <i>rhodorachis</i>)	African racer	Local swelling ± discoloration, bleeding, lymphangitis
<i>Crotaphopeltis hotamboeia</i>	African herald snake	Local swelling
<i>Enhydrys enhydryis</i>	Asian rainbow water snake	Local swelling ± discoloration, lymphangitis
<i>Madagascarophis meridionalis</i>	Madagascan snake	Local swelling ± discoloration, bleeding, blistering, necrosis, lymphangitis, headache, nausea
<i>Malpolon moilensis</i>	African hooded malpolon	Local swelling ± discoloration, lymphangitis
<i>Psammophis sibilans</i>	African racer	Local swelling ± discoloration, bleeding, lymphangitis, headache, nausea
<i>Psammophylax</i> spp. (selected)	African skaapstekers	Local swelling ± discoloration, bleeding, lymphangitis, headache, nausea
<i>Telescopus semiannulatus</i>	African tiger snake	Local swelling ± discoloration, bleeding, lymphangitis, headache, nausea

^aThis list is not exhaustive

in only a few elapids. Some smaller species are unable or unlikely to successfully envenom humans; however, essentially all the larger species are capable of causing envenoming, and many are potentially lethal (Table 4). Elapids are a major cause of snakebite morbidity and mortality globally.

Family Lamprophiidae, Subfamily Atractaspinae

It is a small subfamily of venomous snakes found solely in Africa and the Middle East (Fig. 6); atractaspines are characterized by side-striking fangs (Fig. 7) and unique venom components

Fig. 4 Approximate global distribution of elapid snakes, including sea snakes (Copyright © Dr. Julian White)

Fig. 5 Diagrammatic representation of a typical elapid snake head and fang position (Copyright © Dr. Julian White)

enables the fangs to fold away against the roof of the mouth and thus permits longer fangs in proportion to head size (Fig. 9). There are two major groups of vipers; the subfamily Viperinae contains the classic vipers of the “Old World” (Fig. 9; Table 6), and the pit vipers, subfamily Crotalinae, are characterized by their anteriorly placed heat-sensitive pit organs, which can detect prey by their heat signature (Figs. 10 and 11; Table 7). Vipers are probably the most important cause of global snakebite morbidity and mortality.

(sarafotoxins), but only a few species appear to be able to significantly envenom humans (Table 5) [1, 4].

Family Viperidae

It is a large and diverse family of exclusively venomous snakes covering most continents (except Australia, New Guinea, and Antarctica) (Fig. 8); viperids have a highly evolved fang structure [1, 4]. The fangs are at the front of the mouth, attached to a mobile maxilla, which

Epidemiology of Snakebite

No precise figures on the extent of global snakebite are available. One of the most recent estimates is 2.54 million venomous snakebites and at least 125,000 deaths per year [5]. A subsequent study, using different methodology, estimated venomous snakebite cases as 0.42–1.84 million/year, with 20–94,000/year fatalities [6]. However, subsequent detailed studies in India, as part of the “million deaths” research, determined that in India alone there were at least 45,500 snakebite deaths every year, which indicates the

Table 4 Major groups of elapid snakes and their principal clinical effects

Scientific name	Common name	Effect
<i>Acanthophis</i> spp.	Australian death adders	Neurotoxic paralysis
<i>Austrelaps</i> spp.	Australian copperheads	Neurotoxic paralysis
<i>Aspidelaps</i> spp.	African coral snakes	Neurotoxic paralysis
<i>Bungarus</i> spp.	Asian kraits	Neurotoxic paralysis, myolysis (only some species), hyponatremia (only some species)
<i>Calliophis</i> spp.	Asian coral snakes	Neurotoxic paralysis
<i>Dendroaspis</i> spp.	African mambas	Neurotoxic paralysis and muscle fasciculation
<i>Elapsoidea</i> spp.	African garter snakes	Local effects only
<i>Hemachatus haemachatus</i>	African rinkhals spitting cobra	Local tissue injury, paralysis
<i>Hoplocephalus</i> spp.	Australian broad-headed snakes	Coagulopathy and hemorrhage
<i>Micropechis ikaheka</i>	New Guinea small-eyed snake	Paralysis, coagulopathy, myolysis
<i>Micrurus</i> spp.	American coral snakes	Depending on species, paralysis and/or myolysis
<i>Micruroides euryxanthus</i>	Arizona coral snake	Neurotoxic paralysis (rarely severe)
<i>Naja</i> spp.	African and Asian cobras	Depending on species, severe local tissue injury and/or paralysis
<i>Notechis</i> spp.	Australian tiger snakes	Paralysis, coagulopathy, myolysis, renal damage, hyponatremia (rare)
<i>Ophiophagus hannah</i>	Asian king cobra	Paralysis, local tissue injury
<i>Oxyuranus</i> spp.	Australian taipans	Paralysis, coagulopathy, myolysis, renal damage
<i>Paranaja multifasciata</i>	African burrowing cobra	Local effects only
<i>Pseudechis</i> spp.	Australian mulga and black snakes	Depending on species, myolysis, coagulopathy (anticoagulant), renal damage
<i>Pseudohaje</i> spp.	African tree cobras	Local effects only
<i>Pseudonaja</i> spp.	Australian brown snakes	Coagulopathy, renal damage, rarely paralysis
<i>Tropidechis carinatus</i>	Australian rough-scaled snake	Paralysis, coagulopathy, myolysis, renal damage
<i>Walterinnesia aegyptia</i>	Middle East desert black snake	Neurotoxic paralysis
Various	Sea snakes	Paralysis and/or myolysis

Kasturiratne [6] estimates are significantly too low [7]. On this basis a global annual death toll from snakebite of at least 100,000 seems likely. Certain areas are at high risk, particularly the rural tropics. Unfortunately, these areas coincide with those that have the least medical and financial resources, and thus the fatality rate is higher than would occur if modern medical care and antivenoms were universally available. Certain species groups are responsible for very high numbers of cases and deaths. Of particular note are the saw-scaled or carpet vipers of the genus *Echis* (Fig. 12), which are found from West Africa to

the Indian subcontinent and are possibly responsible for more than 100,000 bites and 10,000 deaths annually. Also important are Russell's vipers (*Daboia russelii* and *D. siamensis*) (Fig. 13), found from Sri Lanka to Southeast Asia; the puff adder (*Bitis arietans*) (Fig. 14), related species in many parts of Africa; and numerous cobra (*Naja*) species (Fig. 15) in Africa and Asia. Additional important venomous snakes are the krait species (*Bungarus*) (Fig. 16), found from Sri Lanka to Southeast Asia; the Malayan pit viper (*Calloselasma rhodostoma*) (Fig. 17) in Southeast Asia; and pit vipers of the genera

Fig. 6 Approximate global distribution of atractaspine snakes (family Lamprophiidae, subfamily Atractaspinae) (Copyright © Dr. Julian White)

Fig. 7 Diagrammatic representation of a typical atractaspine snake head and fang position (Copyright © Dr. Julian White)

Trimeresurus (Fig. 18) and *Gloydius* (Fig. 19) in Asia and *Bothrops* (Fig. 20), *Crotalus* (Fig. 21), and *Agkistrodon* (Fig. 22) in the Americas. Although Australian elapids have a fearsome reputation, they cause relatively few bites and very few deaths and are thus comparatively unimportant.

Those most at risk for snakebite are rural workers, especially while toiling in fields or rice paddies. Some areas, particularly rice-growing regions such as Southeast Asia, have a major seasonal peak of bites during harvest time. Indeed, in much of the rural tropics globally, snakebite is predominantly an occupational disease. Although

Table 5 Atractaspine snakes and their principal clinical effects

Scientific name	Common name	Effect
<i>Atractaspis</i>	African mole or side-fanged vipers	Depending on species, may cause local effects, necrosis, cardiotoxicity

snakebite can occur at any time of the year in tropical regions, it tends to show a seasonal fluctuation, but in temperate climates, where venomous species may hibernate, legitimate snakebites (those not caused by deliberate handling or provocation of the snake) are a phenomenon of the summer or warmer months.

Particularly in Western countries, where keeping venomous snakes attracts hobbyists, some less careful than others, illegitimate snakebites (those caused by deliberate handling or provocation of the snake or by a captive snake) are an important problem that often involves severe bites from exotic species for which no appropriate anti-venom may be readily available. Such hobbyists have in the past enjoyed a reputation for

Fig. 8 Approximate global distribution of viperid (including crotaline) snakes

Fig. 9 Diagrammatic representation of a typical viperid snake head and fang position (Copyright © Dr. Julian White)

recklessness and almost an encouragement of bites, the numbers of which were sometimes “worn” as a badge of honor. It is often assumed by health professionals that this attitude is as inevitable as the numerous bites. It is my experience in South Australia that such need not be the case and that with correct education and encouragement, private keepers of venomous snakes can be very careful and responsible and can work with health authorities to minimize legitimate bites and

provide assistance in identifying snakes that have caused envenoming. This is therefore a plea to my medical colleagues to abandon the past, often hostile relationship between keepers and doctors and seek to establish a good, mutually respectful working relationship that reinforces an ethos among keepers that being bitten is something to be ashamed of and to be avoided at all cost.

Snake Venoms

Snake venoms are generally produced in specific venom glands derived from the salivary glands, the exception being Duvernoy’s glands in some NFFC snakes [1, 4]. The venom, once produced, is delivered by a duct to the fang base, where it is transported into the victim either by a groove in the fang or through a fang duct. Production of intraglandular pressure by contraction of muscles around the gland is the usual mode of venom transport, and this mechanism often allows the snake to “fine-tune” how much venom is expended in a given bite. This may explain, in part, why many venomous snakes exhibit the “dry bite” phenomenon whereby a bite fails to inject

Table 6 Major groups of Viperid snakes and their principal clinical effects

Scientific name	Common name	Effect
<i>Atheris</i> spp.	African bush vipers	Nothing significant
<i>Bitis</i> spp.	African puff adders, Gaboon vipers, etc.	Depends on species, but some cause severe local tissue injury, coagulopathy and hemorrhage, shock, cardiotoxicity, a few cause at least mild neurotoxicity (<i>B. atropos</i>)
<i>Causus</i> spp.	African night adders	Local effects, paralysis
<i>Cerastes</i> spp.	African horned adders	Local effects, coagulopathy, hemorrhage, shock
<i>Daboia russelii</i> and <i>D. siamensis</i>	Russell's viper	Local effects, coagulopathy hemorrhage, and in specific populations/ regions, renal failure, paralysis, myolysis, Sheehan's syndrome, capillary leak syndrome
<i>Echis</i> spp.	African and West Asian saw-scaled vipers	Local effects, coagulopathy, hemorrhage, shock
<i>Macrovipera</i> spp.	Eurasian vipers	Local effects, coagulopathy, hemorrhage, shock
<i>Pseudocerastes</i> spp.	Middle East horned Vipers	Paralysis
<i>Vipera</i> spp.	European vipers	Local effects, necrosis, shock

enough venom to cause medically significant envenoming. Those NFFC snakes producing venom in Duvernoy's glands may have less fine control of venom ejection as these glands are low-pressure glands, unlike the high-pressure glands of FFV snakes (elapids, vipers, atractaspines) [1].

**Fig. 10** Crocrotaline snake head showing fangs in the erect position (Copyright © Dr. Julian White)**Fig. 11** Typical crocrotaline snake head showing the position of heat-sensing pit organs (Copyright © Dr. Julian White)

Snake venoms generally consist of a complex mixture of substances, each of which may exhibit one or more distinct toxic actions [4]. Many of the most potent snake toxins have evolved highly specific targets, such as the neuromuscular junction or components of the hemostatic system. It is likely that all snake venoms fulfill multiple functions for the snake, principally:

- Prey acquisition
- Defense against predators

A third possible function, predigestion of prey, though logical and possible, remains largely unproven.

Table 7 Major groups of Crotalid snakes and their principal clinical effects

Scientific name	Common name	Effect
<i>Agkistrodon</i> spp.	North American copperhead, cottonmouth, cantil	Local effects, necrosis, coagulopathy, hemorrhage, shock
<i>Atropoides</i> spp.	Central American jumping pit vipers	Local effects, necrosis
<i>Bothriechis</i> spp.	Central American palm pit vipers	Local effects, necrosis, shock
<i>Bothrops</i> spp.	South and Central American pit vipers	Depends on species, but may include local effects, necrosis, coagulopathy, hemorrhage, renal damage, myolysis, shock
<i>Calloselasma rhodostoma</i>	Malayan pit viper	Local effects, necrosis, coagulopathy, hemorrhage, renal damage, shock
<i>Cerrophidion</i> spp.	Central American montane pit vipers	Local effects, necrosis
<i>Crotalus</i> spp.	Rattlesnakes	Depends on species; in North America, local effects, necrosis, coagulopathy, shock + paralysis (in a few species); in South America, local effects, paralysis, coagulopathy, myolysis, renal damage
<i>Deinagkistrodon acutus</i>	Chinese hundred pace viper	Local effects, necrosis, coagulopathy, hemorrhage, shock
<i>Gloydus</i> spp.	Asian terrestrial pit vipers	Local effects, necrosis, coagulopathy, hemorrhage, shock

(continued)

Table 7 (continued)

Scientific name	Common name	Effect

<i>Lachesis</i> spp.	Central and South American bushmasters	Local effects, necrosis, coagulopathy, shock
<i>Ophryacus</i> spp.	Central American horned pit vipers	Local effects, necrosis, shock
<i>Ovophis</i> spp.	Asian montane pit vipers	Local effects, coagulopathy, hemorrhage
<i>Porthidium</i> spp.	Central American montane pit vipers	Local effects, necrosis, shock
<i>Sistrurus</i> spp.	North American pygmy rattlesnakes and massasauga	Local effects, necrosis, rarely hemorrhage
<i>Trimeresurus</i> ^a spp.	Asian green pit vipers	Depends on species; local effects, rarely necrosis, coagulopathy, hemorrhage
<i>Tropidolaemus</i> spp.	Asian tree vipers	Local effects; rarely necrosis, coagulopathy, hemorrhage

^aThe pit viper genus *Trimeresurus*, from Asia, contains many species. Some taxonomists controversially split it up into seven separate genera (*Cryptelytrops*, *Himalayophis*, *Parias*, *Peltopelor*, *Popeia*, *Trimeresurus*, *Viridovipera*), but this split is increasingly considered invalid by taxonomists and so is not listed here. However, recent literature may list both venom research and clinical reports based on this contentious taxonomy

Venom variability among snakes is an important concept, with some medically important species showing marked regional variation in venom activity across their geographic range, and there are examples of variability of venom for a single specimen over time, sometimes seasonal, with ontogenetic variability documented for some species [8] (see later section in this chapter). Snake venoms may be classified in many ways, and some classifications still frequently used in

medical texts are misleading or inaccurate. Foremost among these is the old aphorism that elapids are neurotoxic and viperids are hemorrhagic, a classification that is inaccurate and should be abandoned. Some of the most potent toxins active against human hemostasis are found in certain elapid venoms, whereas some other elapid species cause major local tissue injury at the bite site. Conversely, in a number of viperid species, the principal clinical effect is neurotoxic paralysis, with no or minimal effect on either local tissues at the bite site or the hemostatic system. From a medical perspective, a classification based on clinical effects is generally useful (Table 8) and

Fig. 15 Typical cobra with hood displayed (specimen from Thailand) (Copyright © Dr. Julian White)

Fig. 16 Asian krait (specimen from Thailand) (Copyright © Dr. Julian White)

Fig. 17 Malayan pit viper (specimen from Thailand) (Copyright © Dr. Julian White)

will be adopted in this chapter, but the reader should be aware that more biochemically based classifications of venoms yield a quite different picture (Table 9) and that some medically important toxins from snake venoms have several physiologically distinct actions, each caused by separate regions in the structure of a single toxin.

Neurotoxins

Snake venom neurotoxins are a diverse group of toxins that clinically cause paralytic effects mediated at the neuromuscular junction (in most cases) (Fig. 23). A hundred years ago, snakebite paralysis usually condemned the victim to death from respiratory failure. In the current era of intensive care unit (ICU), management, intubation, ventilation, and other treatment modalities, such an outcome, should be rare; however, in many regions such facilities are unavailable, and thus many snakebite victims still die annually of neurotoxic paralysis.

Presynaptic neurotoxins are generally modified phospholipase A_2 toxins that specifically target the terminal axon of the neuromuscular junction, where they interact with and disrupt the axonal cell membrane, enter the cytoplasm, and then disrupt synaptosome production, causing significant intracellular damage. These toxins first cause release of neurotransmitter and then extensive damage to the axonal structure culminating in complete disruption of production of transmitter synaptic vesicles and thus cessation of transmitter release. Experimentally there is a latency period of about an hour, between the time the toxin binds to the axonal cell membrane and complete cessation of neurotransmitter release. Clinically, this causes a progressive flaccid paralysis, with the onset of signs usually 1+ hours after the bite and progressive paralysis thereafter. Full respiratory paralysis, including paralysis of the diaphragm, may take 3–24 h; once paralysis is complete, the recovery rate is determined by axonal repair and is not influenced by antivenom therapy. It is therefore critical in this type of envenoming to recognize the early signs of paralysis and institute effective antivenom therapy

Fig. 18 Green pit viper (specimen from Thailand) (Copyright © Dr. Julian White)

Fig. 19 Asian Gloydus pit viper (Copyright © Dr. Julian White)

Fig. 20 South American Bothrops pit viper (specimen from Brazil) (Copyright © Dr. Julian White)

before more extensive paralysis becomes irreversibly established (Grade III recommendation). Complete paralysis may take days, weeks, or rarely months to resolve. During this period the victim is dependent on external ventilatory support and is at risk for a number of potentially severe complications. Presynaptic neurotoxins are found in selected elapid and viperid venoms (Table 10).

Postsynaptic neurotoxins are polypeptides of varying size, usually under 12 kd, and they also target the neuromuscular junction. They act extracellularly by binding to the acetylcholine receptor on the muscle end plate and blocking neurotransmitter binding, thus causing paralysis. The cell is not specifically damaged, and therefore this type

Fig. 21 North American *Crotalus* pit viper (specimen from the United States) (Copyright © Dr. Julian White)

Fig. 22 North American *Agkistrodon* pit viper (specimen from Mexico) (Copyright © Dr. Julian White)

of flaccid paralysis is often reversible with anti-venom therapy, even if very extensive. The mode of action may also allow more rapid onset and progression of paralysis, although major paralysis is uncommon earlier than 1 h after the bite. Post-synaptic neurotoxins are present in many elapid and a few viperid venoms (Table 11).

Dendrotoxins and fasciculins are synergistic neurotoxins found in some African mamba venoms. Both toxins target the neuromuscular junction and cause paralysis and muscle spasms or fasciculation. Dendrotoxins target certain potassium channels in the terminal axon membrane, ultimately resulting in overrelease of neurotransmitter molecules that swamp and overstimulate the adjacent muscle end-plate receptors. Fasciculins inhibit or interfere with anticholinesterases in the junctional space, thereby significantly reducing the normal removal

of synaptic acetylcholine. This decreased removal of acetylcholine enhances the effect of dendrotoxins and results in gross overstimulation of the muscle manifested as spasm or fasciculation, thereby effectively paralyzing the victim. Both toxins may exert their effect rapidly, and thus the clinical effects may become apparent in less than an hour after a bite.

Other types of snake neurotoxins are produced, some targeting different areas, but they either are uncommon or have limited or no significant clinical effects, particularly when compared with the foregoing toxins.

Myotoxins

Most snake venom systemic myotoxins are based on phospholipase A₂ and cause systemic myolysis

Table 8 Broad medical classification of Snake Venom activities

Toxin activity type	Clinical effects
Neurotoxin	Flaccid paralysis
Presynaptic	Resistant to late antivenom therapy
Postsynaptic	Often reversed with antivenom therapy
Anticholinesterase	Fasciculation
Myotoxin	
Local	Local muscle damage in bite area
Systemic	Systemic skeletal muscle damage
Hemostatic system toxins	Interference with normal hemostasis causing either bleeding or thrombosis
Hemorrhagins	Vascular wall damage causing bleeding
Nephrotoxins	Direct renal damage
Cardiotoxins	Direct cardiotoxicity
Necrotoxins	Direct tissue injury at the bite site/bitten limb

of skeletal muscle but rarely affect cardiac or smooth muscle. The damage occurs to individual muscle cells with sparing of the basement membrane; thus, regeneration of muscle usually begins about 3 days after the bite and is complete after about 28 days. Experimentally, only slow-twitch fibers regenerate, but this is still unconfirmed in human cases. In the process of muscle destruction, massive release of myoglobin, creatine kinase, and potassium occurs. The former is associated with secondary renal damage and often gross myoglobinuria. Theoretically, antivenom therapy should have no effect if muscle breakdown is already established, but experience in Australia suggests that even late antivenom treatment may reduce the severity of muscle damage (Grade III recommendation). Myotoxins are found in both elapid and viperid species (Table 12).

Some snakes, particularly some of the pit vipers such as North American rattlesnakes, possess locally acting myotoxins that do not result in systemic myolysis, but are involved in local tissue injury around the bite site.

Table 9 Broad biochemical classification of snake venom activities

Toxin class	Clinical effects
Polypeptide toxins	Various; autonomic, neurotoxic, cardiotoxic, myotoxic

Toxins Affecting Blood Coagulation

The human hemostatic system seems to be a favorite target of snake venoms. There are toxins targeting almost all parts of the system, as represented in several snake families (Colubridae, Natricidae, Lamprophiidae, Elapidae, Viperidae) [1, 9]. Major toxin groups include procoagulants, anticoagulants, and platelet aggregation inhibitors

Fig. 23 Diagrammatic representation of the neuromuscular junction as target site for snake neurotoxins (Copyright Dr. Julian White)

and promoters (Table 13). The net effect of most of these toxins is to increase bleeding, particularly when combined with hemorrhagins, but a few venoms cause clinical thrombosis with potential for embolic problems. The mechanisms of increased bleeding vary, but most components acting as procoagulants exert their effect by consumption of fibrinogen, which results in defibrination rather than classic disseminated intravascular coagulation (DIC), and thus the

thrombocytopenia associated with DIC may be absent. However, some venoms do cause thrombocytopenia via other mechanisms. Yet other venoms cause defibrination through direct action on fibrinogen by splitting fibrinopeptides inappropriately. The biochemical nature and structure of these diverse toxins vary from comparatively small molecules to large, complex multicomponent toxins that mimic normal clotting complexes such as the prothrombinase

Table 10 Snakes considered to have presynaptic neurotoxins of medical significance (Postsynaptic neurotoxins may also be present in these venoms) (Includes Mamba Dendrotoxins)

Scientific name	Common name	Effect

complex. The majority of viper species have toxins affecting coagulation, but only a few elapid species, notably those from Australia and New Guinea, cause similar effects (Table 14).

Hemorrhagins

In addition to the toxins acting on hemostasis, some venoms, notably those of certain viper species, also contain direct hemorrhagins (Table 15). These toxins damage the vascular endothelium,

thereby promoting bleeding, and are generally zinc metalloproteinases. They are potentially lethal.

Nephrotoxins

Secondary renal damage is common in envenoming by many venomous snake species, but a few species have direct nephrotoxins (Table 16).

Necrotoxins

Local tissue injury around the bite site is a common feature of viperid bites, although not all vipers cause local necrosis. However, certain elapids, notably some cobra species from Africa and Southeast Asia, routinely cause local necrosis (Table 17) [10, 11]. In most cases the venom components causing this damage are incompletely understood, although the ubiquitous phospholipase A₂ toxins are thought to have a major role. The misnamed “cobratoxins” also cause local tissue injury.

Other Toxins

There are, of course, many other components found in snake venoms that are too numerous to list here. For many, the clinical consequences in humans are uncertain.

Venom Toxicodynamics

In recent years it has been possible to measure venom or individual toxins over time in both experimental animals and human snakebite victims. Although such measurement has thus far been performed for only a very limited range of species, there is greater understanding of the

Table 13 Principal types of toxin effects on the hemostatic system [9]

toxicodynamics of envenoming (Fig. 24). In most cases, venom is injected fairly superficially, usually subcutaneously. Locally acting toxins causing tissue injury are placed directly at their target site and will thus begin exerting their clinical effects immediately. A significant proportion of the venom, in some species perhaps most of the venom, will not be absorbed directly into the circulation. Instead, it will be transported first via the lymphatic system and then enter the circulation through the thoracic duct. This helps explain the common clinical finding of enlarged or tender lymph nodes draining the bite area and also the high concentration of venom in these nodes at autopsy. Transport via the lymphatic system may be rapid or sometimes delayed, and there is a potential for sequestration of venom locally with prolonged release over a period of hours or days. Once in the circulation, those components affecting hemostasis or acting as hemorrhagins will have reached their target site and will quickly exert their effect. Similarly, nephrotoxins will quickly damage the kidneys. However, toxins that seek extravascular targets, particularly the neurotoxins and myotoxins, will need to exit the circulation in sufficient concentration to exert

their effect clinically; thus, these toxins are most likely to have a delayed onset of clinically detectable action. Some of these latter toxins also have a significant delay between reaching their target site and causing clinically detectable effects, and thus clinical evidence of their effects may be significantly delayed, even though they may be causing irreversible damage prior to clinical manifestations. Some venoms are quickly cleared from the circulation, but others remain detectable for days or even weeks without antivenom therapy. Knowledge of such variation is clearly relevant in determining antivenom therapy, as will be discussed later.

Venom Variability

It is often assumed by those unfamiliar with clinical toxicology that a given species of snake will have a consistent venom. Though sometimes true, probably more often there is significant intraspecies and even intraindividual venom variability [8]. Some medically important species exhibit great variability in venom throughout their

geographic range, so significant that antivenom developed by using venom from one part of that range will be totally ineffective in treating bites by specimens from another part of the range. Classic examples are Russell's viper (*Daboia russelii*, *D. siamensis*) and the South American rattlesnake (*Crotalus durissus terrificus*). Even a single geographic location may have several distinct subpopulations of venom type. Equally, it is well established that some snake species show either

or both ontogenetic and seasonal venom variability.

Clinical Effects of Envenoming

The clinical effects of a snakebite will vary with the species of snake; the age, size, and geographic origin of the snake; the quantity of venom injected; the route of injection; the age, size, and previous health of the victim; and past exposure to venom. Thus, although there may be typical features of envenoming for a given snake species, there will usually be significant variation between cases [12].

Local Effects

Snakebite may result in very obvious bite marks and a prominent local tissue response, but equally, the bite marks may be indistinct or virtually undetectable and the local response negligible. The latter is particularly true for certain elapid species, but a few viperids also cause minimal local effects and similarly exert their major clinical effects systemically.

Bite marks vary from a single fang puncture (Fig. 25) to classic double punctures from paired fangs (Fig. 26), through numerous punctures from both fangs and nonfang teeth (Fig. 27), to scratches where fangs have dragged through the skin (Fig. 28). If two or more bites have been delivered to the same region, an even more complex pattern may be seen (Fig. 29). The distance between paired fang punctures may indicate the size of the snake but depends on the species; if the snake species is unknown, interfang distance is an unreliable method of predicting snake size.

The presence of associated effects may be of value in determining the most likely culprit. Thus, there may be local swelling (Fig. 30), erythema, ecchymosis (Fig. 31), hemorrhage (Fig. 32), blistering (Fig. 33), or frank necrosis (Fig. 34). In general, it should never be assumed that the lack of a local response to a bite indicates a trivial bite, unless the snake species responsible is already

Table 17 Snakes known to potentially cause significant local tissue injury and necrosis at the bite site [10, 11]

known and is clearly associated with significant local effects in all medically noteworthy cases.

Local pain is quite variable and not always reliable as an indicator of significant envenoming.

General Effects

General systemic symptoms vary among species and individuals but usually include some or all of the following: headache, nausea, vomiting, abdominal pain, diarrhea, dizziness, collapse, and convulsions. Particularly in children, collapse and convulsions may be the first evidence of envenoming, at least for certain species (e.g., Australian elapids). It is often assumed that hypotension will occur in response to envenoming, but hypertension is also common, and both tachycardia and bradycardia are reported.

Specific Effects

In addition to the nonspecific systemic symptoms, a variety of quite specific symptoms and signs is associated with particular venom actions. Recognition of these symptoms and signs in the early stages is important because it allows appropriate

remedial action, usually antivenom therapy, before major complications occur.

Paralysis

The flaccid paralysis caused by neurotoxins affects principally skeletal muscle and respiration, rather than cardiac or smooth muscle, and is a descending paralysis. For species with potent postsynaptic neurotoxins, paralytic symptoms can develop within 3–15 min of the bite and major paralysis within 15–30 min, but such cases are the exception. In most instances, clinically detectable paralysis will not be apparent

until at least 1 h after the bite and may be delayed up to 24 h. The cranial nerves are usually affected first, with ptosis often being the initial sign (Fig. 35). Other common initial signs are dysphonia, dysphagia, drooling, and diplopia, the latter caused by partial ophthalmoplegia (Fig. 36). As paralysis progresses, drooling may increase and ophthalmoplegia may become total, with fixed forward gaze often associated with fixed dilated pupils. Limb weakness becomes apparent, the victim usually first noticing an ataxic gait and then an inability to walk and subsequently an inability to stand or even sit up. The neck may

Fig. 35 Bilateral ptosis, usually the earliest sign of progressive flaccid neurotoxic paralysis (Copyright © Dr. Julian White)

become floppy (“broken neck” sign). Deep tendon reflexes will become reduced and then disappear. Respiratory distress develops, breathing may become shallow and rapid, and cyanosis may be apparent. Complete respiratory failure will ensue unless respiratory support is offered. The time from a bite to respiratory failure is highly variable, from as little as 30 min (rare) to more than 24 h, but commonly within 6–12 h. Without antivenom or anticholinesterase therapy, the period of respiratory failure may vary from less than 24 h to several days or even several weeks.

For species with potent presynaptic neurotoxins but low concentrations of postsynaptic neurotoxins, although the symptoms and signs are the same, the rapidity of onset is usually slower, with the first signs essentially never evident in less than 1 h after the bite. Unless paralysis is diagnosed and halted at an early stage with antivenom therapy, this type of paralysis is not reversible, and days, weeks, or months may elapse before axonal repair is sufficient for return of neuromuscular function.

In addition to the major features just noted, several other neurotoxic effects may occur. Of particular note are transient or permanent alterations in taste or smell, sometimes leaving the victim with permanent partial or complete anosmia.

Myolysis

Muscle damage may sometimes be purely local (some rattlesnake species) but is more commonly

systemic. Onset is likely to be at least 1 h after the bite, but symptoms and signs are mostly delayed considerably longer. Symptoms include muscle pain, tenderness, and weakness, the latter potentially mimicking paralysis. The onset of symptoms is usually associated with detectable, often frank myoglobinuria, with the urine varying from clear red (similar to hemoglobinuria) to deep muddy brown (Fig. 37).

Coagulopathy and Hemorrhagin Effects

The severity and clinical manifestations of coagulopathy will be determined, in part, by the species of snake. In general, the first clinical evidence of coagulopathy is often persistent oozing of blood from the bite site, any other areas of recent trauma, venipuncture sites, and often the

gums. The gums are particularly likely to bleed if hemorrhagins are present in the blood. The area around the bite site may show mild to gross and extensive ecchymosis (Fig. 38). Hematuria may be present; if myoglobinuria is also suspected, microscopic evidence of red cells or casts may assist in differentiation. The coagulopathy may be severe, yet the victim may be virtually symptom-free and thus the severity of envenoming masked. It is particularly because of this danger that at least baseline clotting tests should be routinely performed for most types of snakebite, the exception being regions where none of the culprit species cause coagulopathy. Although full laboratory tests of coagulation might be ideal, in most parts of the world, they are either unavailable or will take a long time. If detailed coagulation studies are unavailable, the 20-min whole-blood clotting test (20WBCT; discussed later) is an invaluable bedside test in snakebite victims. In the presence of major coagulopathy, any trauma has the potential to result in major or lethal hemorrhage, particularly with head injuries.

Fibrin degradation products are cleared through the kidneys, and secondary renal failure is a potential complication of coagulopathy. A few species can cause quite specific hemorrhages; most notably, Russell's viper (*Daboia siamensis*) in Myanmar (Burma) can cause anterior pituitary hemorrhage or Sheehan's syndrome, with long-term and potentially lethal consequences due to panhypopituitarism.

Fig. 36 Partial ophthalmoplegia with divergent squinting and diplopia, as well as ptosis, indicative of progressing paralysis (Copyright © Dr. Julian White)

Fig. 37 Myoglobinuria secondary to systemic myolysis (Copyright © Dr. Julian White)

Fig. 38 Marked hemorrhagic effects in a bitten limb (Copyright © Dr. David Hardy)

Although the net effect of most hemostatically active venoms is functional anticoagulation, often through consumption of fibrinogen, thrombosis is sometimes the most prominent effect. Bites by vipers (*Bothrops lanceolatus*, *B. caribeus*) in Martinique, in particular, are associated with the development of deep venous thrombosis and a significant risk for pulmonary embolism, myocardial infarction, and stroke.

Thrombocytopenia, usually as a delayed onset finding after coagulopathic snakebite, can be severe and resistant to treatment, either further antivenom or platelet transfusion, though where clinically indicated both should be actively considered as therapy (Grade III recommendation). Inadequate doses of antivenom in the acute stage, or using antivenom with rapid clearance, can be associated with late-onset thrombocytopenia, such as with some North American rattlesnake bites.

Another clinical syndrome sometimes associated with coagulopathic snakebites is a microangiopathic hemolytic anemia, generally presenting with a classic triad of thrombocytopenia, intravascular hemolytic anemia, and secondary acute renal failure. This is similar to thrombotic thrombocytopenic purpura or hemolytic uremic syndrome, though the underlying causative pathology may be different. This syndrome has been seen following bites by a variety of Australian elapid snakes, as well as bites by some vipers such as the horned vipers (*Cerastes* spp.).

Nephrotoxicity

Renal damage is a common sequela of bites by many species of snakes and may be primary or secondary and varies from mild transient increases in creatinine and urea levels, detectable only by laboratory tests, through oliguric or anuric renal failure, to rare cases of permanent renal damage (renal cortical necrosis). Careful measurement of urine output is important to detect early evidence of functional renal problems, which are otherwise asymptomatic, at least in the critical early hours after a bite.

Cardiotoxicity

The cardiotoxic effects of a snakebite are primary in only a few species but may occur secondarily after bites by many species; these effects vary from mild arrhythmias to cardiac arrest. Severe myolysis, particularly when associated with secondary renal failure, may result in severe hyperkalemia, with consequent and sometimes lethal effects, as seen with other causes of hyperkalemia.

Management of Snakebite

First Aid

First aid for a snakebite is controversial. Many techniques are promoted or used around the world, but most have in common a complete

lack of objective evidence of efficacy and are often associated with significant adverse side effects varying from delay in obtaining appropriate care to directly related death.

The only universally approved first aid for a snakebite, applicable globally, is immobilizing the bitten area/limb and keeping the victim still, though it is an unproven technique [12, 13] (Grade III recommendation). For bites by nonnecrotic species, including many elapids (but not most cobras) and a few viperids, the Australian-developed pressure immobilization method (pressure bandage + immobilization; PBI) is both safe and effective [12, 14, 15] (Grade III recommendation). It is based on retarding venom transport in the lymphatics by applying moderate local and limb pressure sufficient to occlude the superficial lymphatics and inhibiting the muscle pump transport system by immobilizing the limb in a splint. Applied correctly, it may be safely left on for several hours and experimentally is as effective as a tourniquet in preventing venom movement, but far safer. This technique has not been subjected to clinical trials, although extensive anecdotal evidence from Australia suggests that it is safe and effective when used correctly [15]. More recently, a study has shown that using the originally recommended crepe bandages are unlikely to result in effective compression in humans, while use of an elasticized bandage is far more likely to be effective [16]. This study has not been tested in envenomed patients, so it remains unconfirmed, but logical. A modification of the technique using a local pressure pad over the bite site has been tested for viper bites in Myanmar, and the initial results suggest promise, with no increase in local tissue injury [17]. This method is now the recommended first aid for snakebite in Myanmar, and there is no evidence published indicating it is associated with increased local tissue damage. If these studies are extended to other necrotic bites without evidence of increased necrosis, the pressure immobilization method, or possibly the pressure pad method, may become the universally accepted first aid for all snakebites. That it is not presently accepted universally reflects concern that

immobilizing necrotic venom locally may worsen the extent of necrosis and thus be counterproductive in treating the victim. A further additional method to reduce local lymphatic flow has been proposed, based on experiments in a rat model, applying nifedipine or lignocaine topically, to be used in association with pressure bandaging and immobilization, though no human studies to confirm benefit have been published [18].

In general, the bite wound should be gently cleaned, except where bite site venom detection is available, as in Australia and New Guinea. Clear fluids may be given by mouth, but not food and certainly not alcohol.

Tourniquets are no longer recommended for snakebite (Grade III recommendation) because they are easily misused, are effective for too short a period, and have a high and proven potential for causing severe injury to the victim through ischemic necrosis [12]. The resulting gangrene may prove lethal, and the personal and social cost of amputated limbs is devastating. Suction applied to the bite site is inappropriate (Grade III recommendation) [12]. If mouth suction is used, active venom may be transferred to the oral cavity and bacteria instilled in the wound. Contrary to many positive claims, dedicated suction kits remove only small and often negligible quantities of venom and may disrupt local tissues and thereby promote spread and absorption of venom. Cutting the wound or, worse still, excision only adds further injury to the victim, increases the absorption of venom, and provides an avenue for major hemorrhage if a coagulopathy is present [12]. Application of local electric shock, as used in parts of the Americas and Africa, has never been shown in either experimental studies or clinical trials to be other than a charlatan treatment [12]. Similarly, the use of cryotherapy is without merit and associated with tissue damage [12]. Traditional healing, such as snake stones, has no rational basis, but it is possible that certain native plant extracts may ultimately prove beneficial. However, until their safety and effectiveness have been conclusively demonstrated, they cannot be recommended.

Hospital Treatment

In regions where effective hospital care is available, it should be the cornerstone of snakebite treatment. The hospital management of specific snakebites is discussed in considerable detail in the following chapters. Unfortunately, in many snakebite-prone areas, such treatment is not reliably available.

Some Basic Principles

Whenever possible, the first priority is to critically assess and stabilize the vital systems if imperiled. Thus, attention to the airway, breathing, and circulation should take priority. However, if there is a possibility of coagulopathy, attempts at cardiac compression should be circumspect and instituted only if absolutely indicated.

An intravenous (IV) line should be inserted and, in most cases, an initial IV fluid load given, especially in cases in which significant local reaction is occurring with consequent fluid shift and the potential for hypovolemic shock (Grade III recommendation). The choice of IV fluids will depend on the circumstances and availability.

Particularly in victims likely to have a coagulopathy necessitating repeated assessment of coagulation, insertion of a line suitable for repeat sampling, rather than performing repeated venipunctures, should be considered. The femoral, jugular, and especially the subclavian vessels should be avoided.

Diagnosis

As in other diseases, diagnosis is crucial in effective management of a snakebite [12]. Three principal diagnostic questions should be asked: is this a snakebite or some other condition? If it is a snakebite, is significant envenoming present and to what extent? And, finally, what type of snake was responsible?

The diagnosis of snakebite may be obvious, as in patients seen after being bitten by their pet snake, but such cases are the exception. Usually, however, it is likely that the identity of the snake is unknown. Also, there are numerous cases without a history of a bite, just a set of symptoms to be

explained, where snakebite may not even be thought of initially.

History. The key features required when taking a history from a suspected snakebite victim are as follows:

- Time and geographic location where the bite did or might have occurred (time since the bite is important, and geographic location may limit the number of possible snake species).
- If a snake was seen, its description, particularly its color, pattern, and length.
- If a bite was witnessed, was it a single or multiple bite? (A multiple bite is much more likely to be severe.)
- Was first aid applied, what type of first aid was it, how long after the bite was it applied, and what did the victim do between being bitten and application of first aid? (If the victim was actively chasing the snake or was escaping from the snake before application of appropriate first aid [e.g., immobilization or, for nonnecrotic species, pressure immobilization], first aid was unlikely to have been effective; thus, if the victim is not envenomed at initial hospital evaluation, it is more likely to be a dry bite. If, in contrast, the victim immediately lay still and had appropriate first aid applied, the lack of envenoming at initial hospital assessment may simply mean that the first aid was effective; in such cases, envenoming may rapidly ensue once first aid measures are removed.)
- Are there any nonspecific symptoms suggestive of envenoming, such as headache, nausea, vomiting, abdominal pain, fasciculations, collapse, or convulsions?
- Are there any symptoms suggestive of ongoing major envenoming, such as “tired/sleepy eyes (ptosis) and blurred or double vision; difficulty speaking, swallowing, walking, or breathing; bleeding from the bite site; or muscle pain?
- Is there any relevant past history, such as past exposure to antivenoms; preexisting cardiac, respiratory, renal, or allergic disease; or recent surgery or trauma?

- Is the patient taking any medications, particularly those that might interfere with key blood tests (especially anticoagulants)?

Examination. Careful examination can often be vital in determining the extent of envenoming.

Local Signs

- Examine the bite site and look particularly for evidence of multiple bites. Fang marks may be single or double punctures or scratches when fangs have dragged through the skin, and they are sometimes very small and difficult to see, particularly with colubrids and smaller elapids. Also look for local swelling, bruising, discoloration, blistering, and developing necrosis, typical of bites by certain species. For locally active venoms, such as bites by many viperid species, the rapidity and extent of swelling may indicate the probable severity of envenoming.

General Signs

- Check the draining lymph nodes for tenderness or swelling, which may indicate absorption of venom.
- Check the pulse and blood pressure (systemic envenoming often causes hypertension).

Specific Signs

- Check for evidence of paralysis, such as ptosis, partial or complete ophthalmoplegia, fixed dilated pupils, flat facies, poor tongue protrusion, dysarthria, drooling, limb weakness, poor grip strength, reduced or absent deep tendon reflexes, paralytic-type respiratory difficulties, and cyanosis.
- Check for evidence of coagulopathy and hemorrhagin activity, such as persistent oozing of blood (not serosanguineous) from the bite site, extensive local ecchymosis, hemorrhagic blistering, and persistent bleeding from venipuncture sites, gums, recent trauma, or elsewhere. When appropriate (e.g., viper bite in Martinique), check for evidence of developing deep venous thrombosis. When appropriate (e.g., Russell's viper bite in Myanmar), check for evidence of anterior pituitary hemorrhage and secondary panhypopituitarism (develops late).

- Check for evidence of myolysis, such as muscle tenderness or weakness and red or brown urine (myoglobinuria).
- Check for evidence of renal impairment, such as oliguria or anuria.
- Check for evidence of cardiac abnormalities, particularly arrhythmias or electrocardiographic changes associated with hyperkalemia.

Laboratory Investigations. Laboratory tests are often very helpful in determining the extent of envenoming, but this does not mean that only a large hospital with a well-equipped laboratory can manage a snakebite. It is also vital to repeat tests, even if the results are initially normal. If the patient's initial examination and test results are normal and thus indicative of no current envenoming, the tests should be repeated in about 2 h and then again 3 h later (fifth hour after initial assessment) to ensure that the late development of envenoming, particularly coagulopathy, is not missed. In Australia a schedule of testing (clinical examination and laboratory tests) has been recommended; first test on initial presentation and, if normal, remove first aid and retest after 1 h; if normal, retest at 6-h post-bite and, if again normal, retest at 12-h post-bite; if throughout the patient has experienced no symptoms, signs, or laboratory abnormalities suggestive of envenoming, then they can be discharged, but with a caveat – in some areas where death adder bite is possible – a longer period of observation (24 h) may be justified to detect late developing paralysis (Grade II-2 recommendation). In some situations, especially some viper bites causing coagulopathy (notably the Malayan pit viper bite), envenoming may persist, develop late, or recur after antivenom therapy, so retesting over a period of several days may be required. Earlier testing is indicated if symptoms or signs develop.

A Small or Rural Hospital. Many snakebite victims will initially go to a small rural hospital with no laboratories on site. However, there are some very useful tests that can easily be performed:

- Urinalysis to look for hemoglobin/myoglobin (both test positive for blood). Simple microscopy to search for red cells or casts may help

differentiate between hemoglobinuria and myoglobinuria.

- Whole-blood clotting time and 20WBCT. This simple but effective test requires at least two standard clean *glass* test tubes or similar glass containers. A small quantity of the patient's blood (2–3 ml) is placed in one tube, a similar amount of blood from a normal control (relative or staff member) is placed in another tube, and the time taken to clot is measured. If normal, the blood should clot in 5–10 min. If just the patient's blood fails to clot or develops only a weak clot by 15 min, a coagulopathy is probably present. If neither the patient nor the control blood clots, there is a problem with the test system. It has been suggested that this test can be simplified by checking for clots only once, 20 min after taking the sample (20WBCT); a normal clot indicates no coagulopathy, whereas a weak or no clot indicates coagulopathy. The 20WBCT is now a standard test for snakebite coagulopathy in many countries and has been validated [19–21]. A recent study has questioned reliability of this test, though without providing a viable alternative if no formal coagulation testing laboratory is readily available [22].
- Only in Australia, detection of snake venom on the bite site swab (see “Venom Detection” in ► Chap. 122, “Australian and Pacific Snakes”).

A Regional or Teaching Hospital. If full laboratory facilities are available, use them! The following should be performed, labeled urgent:

- Extended coagulation studies: prothrombin time/international normalized ratio (INR), activated partial thromboplastin time (aPTT), fibrinogen level, and cross-linked or D dimer degradation products of fibrin/fibrinogen
- Complete blood picture, especially platelet and absolute lymphocyte counts
- Electrolytes, urea, and creatinine
- Creatinine phosphokinase
- Where appropriate, arterial blood gas determination

- Examination of a peripheral blood smear for evidence of microangiopathic hemolysis, suggestive of DIC
- Only in Australia, detection of snake venom on the bite site swab (see “Venom Detection” in ► Chap. 122, “Australian and Pacific Snakes”)

Snake Venom Detection. Currently, the only commercial venom detection system is the Australian CSL Snake Venom Detection Kit (SVDK; Seqirus (previously bioCSL Ltd), Melbourne, Australia), which relies on a sensitive sandwich enzyme-linked immunosorbent assay to detect even small concentrations of snake venom. It has been in use for over 30 years and can detect even nanogram concentrations of venom, but it is applicable only for snakes native to Australia and New Guinea [23]. The best sample is a moist swab from the bite site. If systemic envenoming has occurred, urine may be tested if a bite site is not available. Blood is the least reliable test sample and should be avoided if possible. The kit gives only a qualitative result and is designed just to detect which type of venom immunotype is involved, to allow use of specific rather than polyvalent antivenom. It is not a screening test for snakebite or envenoming. A negative result does not exclude envenoming, and a positive result does not indicate either significant envenoming or a need for antivenom therapy.

A number of experimental venom detection systems have been used in various regions of the world, and it is possible that commercial snake venom detection will become more widely available in the future. Some of these detection systems may be quantitative as well as qualitative, which will give far more scope to studying the extent of systemic envenoming and may lead to far more precise guidelines on antivenom doses. However, where the only antivenom choice is polyvalent, the incentive to develop or use venom detection is likely substantially reduced.

Differential Diagnosis

The differential diagnosis issues surrounding snakebite are most commonly those including snakebite in the differential diagnosis of unexplained collapse, convulsions, coagulopathy, paralysis, myolysis, or renal failure.

Treatment of Snakebite

Treatment of snakebite is likely to be effective only if the extent and nature of the envenoming are known, hence, the importance of the diagnostic process discussed earlier.

Basic Treatment

The basics of management were listed earlier and include an IV line, initial IV fluid load, and attention to the airway, breathing, and circulation. Avoid accessing the femoral, jugular, or subclavian vessels because bleeding associated with coagulopathy may be extreme (Grade III recommendation). Keep venipunctures to a minimum (Grade III recommendation). Frequent blood tests are usually required, so consider insertion of a long line via the cubital fossa or even a radial arterial line, particularly if ICU facilities are available. Monitor the pulse, blood pressure, respiration, and cardiac rhythms regularly, preferably with appropriate monitors. Monitor urine output; if in any doubt, especially in adults, consider inserting a urinary catheter, but beware insertion trauma issues if there is a coagulopathy.

Ensure that the patient is regularly assessed for evidence of developing paralysis, coagulopathy, myolysis, or renal failure, even if initially perfectly well.

Antivenom Therapy

Antivenom is the only specific therapy for envenoming (Grade III recommendation) [10–12, 15, 20–29]. Used correctly, it is arguably effective, comparatively safe, cost-effective, and lifesaving. Used incorrectly, it is ineffective, potentially lethal, costly, and may not save lives.

Antivenom is an essentially refined antibody against venom antigens. Some newer antivenoms are Fab or F(ab')₂ fragments of IgG molecules. Such antivenoms have a reduced rate of immediate or delayed (serum sickness) reactions when compared with standard whole-antibody

preparations. Newer techniques, notably caprylic acid purification, can render whole IgG-based antivenoms comparatively safe, potentially similar to Fab or F(ab')₂ antivenoms, but at a fraction of the cost and without the rapid clearance problems associated with Fab-based antivenoms. In most countries, snake antivenom is raised in horses and is thus refined horse serum. Ovine (sheep-based) antivenom is in use (e.g., CroFab in North America) and appears to have a reduced rate of adverse reactions, at least as a highly refined Fab antivenom, with correspondingly high production costs. Less-expensive ovine-based antivenoms may be useful, but there are safety issues in using sheep in many parts of the world that have ensured horses remain the mainstay for antivenom production. Other animals, such as goats, camels, and even rabbits, have been used in either commercial or experimental antivenoms, but remain marginal as a production source. All antivenoms, particularly equine antivenoms, may cause both immediate and delayed allergic reactions. These reactions are discussed later (see section “[Complications of Antivenom Therapy](#)”). Because of these potential complications, antivenom should be used only when clearly indicated. However, the risk of antivenom reactions is usually far less than the risk of untreated envenoming; *never* withhold antivenom from a patient who needs it because of concern about reactions to antivenom!

When to Use Antivenom

Antivenom should be used only if there is clear evidence of systemic envenoming and then as soon as safely practical (Grade III recommendation). Absolute indications would be:

- Significant coagulopathy
- Any degree of paralysis
- Significant myolysis (generally, creatinine kinase > 1500 IU/L)
- Any degree of renal damage
- Rapidly advancing severe local effects (some vipers such as rattlesnakes)
- A patient with a known snakebite who had a period of collapse or convulsions before arrival

More difficult are the general symptoms, such as headache, nausea, vomiting, and abdominal pain, which may indicate either envenoming (though not necessarily severe) or anxiety. In general, these symptoms alone would not be an indication for antivenom. However, guidelines must be tailored to particular circumstances; for instance, a patient with Russell's viper bite in parts of Asia might receive antivenom if any evidence of possible envenoming developed, because of the high risks associated with delayed therapy.

Choosing the Right Antivenom

A specific antivenom for the snake involved is always preferable to a polyvalent antivenom for two major reasons:

- The specific antivenom will usually be lower volume, so the risk of reactions, particularly serum sickness, is reduced, and volume overload, important in small children, is less severe.
- Specific antivenoms are generally cheaper than polyvalent antivenom.

However, specific antivenoms can be used only if the identity of the snake is known, which may be achieved in several ways, some more reliable than others:

- A visual description of the snake. Such identification is unreliable in many circumstances and is generally a poor basis for choosing a specific antivenom. There are exceptions to this in particular regions, such as areas in Asia where Russell's viper is a major cause of snakebite and is well known by the local population and there are no other snakes with a similar appearance.
- Identification of a captured or killed snake. Quite apart from the dangers posed by trying to identify a live snake or the hazards from fangs in examining a dead snake, most doctors are ill equipped to accurately or reliably identify a snake. An attempt to capture snakes is not recommended given the potential for further envenoming, even by dead snakes (whole and decapitated). Nevertheless, in some parts of the world, it is common

practice to kill the snake and bring it with the patient, and this valuable resource should not be overlooked or hastily discarded.

- Venom detection (only available in Australia). This method is generally preferred, where available. It is mostly reliable, but not every patient with systemic envenoming will have a positive SVDK result. Occasionally, erroneous results occur. Be sure that the clinical and laboratory pattern of envenoming fits the SVDK result. If it does not, urgently seek expert advice!
- Combination of geographic location and local and systemic effects. These criteria have been developed for some regions in recent years based on studies of the effects of envenoming by each species in the region (e.g., Australia, Southeast Asia). There will always be occasional atypical cases that will render such systems less effective, but in expert hands, this type of diagnostic algorithm is the most effective [20, 21, 23].

If all the aforementioned methods fail to give a reliable result, there are two remaining choices. If the range of snake species in the area is limited, it may be possible to create a local "polyvalent" antivenom by mixing two appropriate specific antivenoms. The other alternative is to use a polyvalent antivenom. In some regions this is the only choice.

Determining the Dose of Antivenom

The quantity of antivenom required is variable and depends on the type of snake, the size of the snake, and the number of bites. Children require the same dose as adults (Grade II-2 recommendation).

Administering Antivenom

Snake antivenoms should always be given IV (Grade III recommendation). There is one school of thought that they should be diluted up to 1:10 in saline or a similar diluent and then administered over a 15- to 20-min period. Infusions should start slowly under close medical observation, and the rate gradually increased. Experience and limited evidence indicates this is not the only valid

approach, and in some parts of the developing world, where IV diluted infusions may be impractical, a slow push neat antivenom injection IV is the standard of care and does not seem to be associated with higher rates of adverse reactions.

Before giving antivenom, have everything prepared to treat anaphylaxis should it occur, particularly epinephrine (adrenaline). If available, it may be advisable to have an infusion pump set up for an epinephrine infusion and ready to piggyback into an IV line if anaphylaxis develops. Premedication before administration of antivenom is no longer a recommended practice in most regions, but this is changing. Epinephrine premedication is potentially hazardous and of uncertain value, but some recent trials have indicated that, at least for some antivenoms with high rates of adverse reactions, premedication with subcutaneous adrenaline is beneficial, while others have not found a clear benefit [30–35]. Based on this conflicting evidence, it appears reasonable to consider using epinephrine premedication SC prior to giving antivenom, at least in a setting where health/hospital resources may be suboptimal (Grade II-1 recommendation). Antihistamines and hydrocortisone are of no proven value. Pretesting for antivenom allergy, as used in North America in the past, is a useless and potentially dangerous practice because it can directly cause anaphylaxis and can fail to predict anaphylaxis, and it can sensitize the patient, causing problems on subsequent antivenom exposure; hence, pretesting for antivenom sensitivity should not be performed (Grade III recommendation).

Complications of Antivenom Therapy

The immediate adverse effects of antivenom therapy are threefold:

- Rash
- Biotoxin-based fever
- Anaphylaxis or anaphylactoid reaction

The rate of adverse reactions to antivenom is variable and appears to be dependent, at least to some extent, on the type of antivenom (how the antivenom is produced and who the producer is).

In general terms, unprocessed whole equine IgG antivenoms are historically associated with the highest rate of adverse reactions, including anaphylaxis, while highly refined Fab and F(ab')₂ antivenoms have lower rates of adverse reactions, and possibly ovine antivenoms may cause fewer adverse reactions than the same class of equine antivenoms.

Rashes are the most frequent reaction, but they are still uncommon for most antivenoms. They may herald anaphylaxis.

Febrile reactions are rare with some antivenoms, because of high manufacturing standards, but may be higher with antivenoms produced to a lower standard.

Anaphylaxis or anaphylactoid reactions, though rare (probably less than 1% of cases) with good-quality antivenoms, are potentially lethal. However, some antivenoms have high rates of adverse reaction, with rates higher than 80% noted for some products, particularly those containing unrefined IgG. Reactions to antivenom, including anaphylactic-like reactions, can occur on first exposure and are thus clearly not mediated by IgE and are not predictable. Accordingly, major life-threatening reactions to antivenom should always be anticipated and preparation for treatment made before commencing the antivenom infusion (Grade III recommendation). There are three major manifestations of these major early reactions: hypotensive shock, bronchospasm, and angioneurotic edema. They should be treated the same as for any other cause of anaphylaxis, that is, with epinephrine (very cautiously IV, via an infusion pump, or subcutaneously [SC] or intramuscularly [IM]: 6 mg/100 mL at 10 mL/h for the infusion pump or 0.5 mL SC or IM for adults, 0.01 mg/kg SC or IM for children), oxygen, IV fluids, or inhaled epinephrine for bronchospasm via a nebulizer (e.g., 2 mL of a 1:1000 solution). The antivenom infusion should be stopped while the anaphylaxis is being treated and then cautiously restarted once the reaction is controlled, with titration of epinephrine versus antivenom as required.

Delayed effects of antivenom therapy are also uncommon for many antivenoms. The only effect

of general significance is serum sickness, which may occur 4–14 or more days after exposure to antivenom and is characterized by rash, joint pains, fever, and malaise. It is treated with steroids and/or antihistamines. Though of unproven value, in some parts of the world, it is common to prescribe a 5- to 7-day course of oral steroids to every patient who has received a significant dose of antivenom (>25 mL in total) in the hope of preventing serum sickness (Grade III recommendation).

Non-antivenom Therapies

Only antivenom can neutralize venom. Few other treatments are available. For predominantly or wholly postsynaptic neurotoxins (such as bites by death adders, some coral snakes, Australian copperheads, selected cobras such as the Philippines cobra), temporary improvement can be achieved with an anticholinesterase (e.g., neostigmine), which is useful if paralysis is severe or antivenom is not immediately available.

Local infection after a snakebite varies with the species and region. In many areas, infection is the exception, so routine prophylactic antibiotics are inappropriate (Grade III recommendation). However, some snake species, notably some of the pit vipers, seem to regularly cause local infection at the bite site. The organisms involved are variable and often atypical, and culture and sensitivity studies are advisable before commencing treatment.

As discussed later, coagulation factor replacement therapy is generally inadvisable for snakebites.

Local swelling may be absent after bites by some species, notably many elapids, but it is a common feature of envenoming by some elapids (e.g., some cobras) and most (but not all) viperids and crotalids. Although the extent of local underlying tissue injury can be severe, even for most viperids and crotalids, there is rarely any underlying compartment syndrome, and fasciotomy is hardly ever required. It should be performed only if there is absolute evidence of a

compartment syndrome, such as intracompartmental pressure measurements, and any coagulopathy has been controlled (Grade III recommendation) [20, 21, 36, 37]. At least for rattlesnake bites, there is a management algorithm for possible compartment syndrome [38].

Antibiotics

In general, antibiotics are recommended only if there is secondary infection, but every attempt should be made to target a detected organism.

Other

Avoid a tetanus booster IM in the presence of coagulopathy, but most patients should have their tetanus immunization status assessed and brought up to date as soon as safe to do so (Grade III recommendation).

Treating Specific Complications of Envenoming

Many potential complications are associated with envenoming, the most important being extension of major venom effects. Only the most common and important are covered here.

Paralysis

The paralysis associated with neurotoxins can present major management problems and secondary complications. It is therefore always best to avoid severe paralysis by detecting the early signs and giving adequate appropriate antivenom (Grade III recommendation). If not possible, perhaps because the patient was initially seen late and had established major paralysis as a result of nonreversible presynaptic neurotoxins (bites by some Australian elapids, some kraits, selected other species), management must focus on maintaining adequate respiration, usually by intubation and mechanical ventilation. Intubation is preferable to tracheostomy (Grade III recommendation), at least in the short term, not least because tracheostomy is a potentially lethal procedure if coagulopathy is present. Though paralyzed by the venom, the patient may be fully awake. Such

patients require careful nursing and verbal reassurance during this period. It is helpful to talk to them, explain where they are and what is happening, and manually open their eyes and rotate their head so that they can see their surroundings and caregivers. Try to find some part of their body that they can move enough to indicate “yes” and “no” to establish a means of communication. Some patients will require sedation. There is a significant risk of secondary pulmonary infection. The period of complete paralysis is highly variable, from a few days to several months. Even after respiratory function has returned, there may be continued general weakness, and the cranial nerves are sometimes even slower to recover. Occasionally, permanent damage may occur and affect taste or smell or both.

When paralysis is due to purely postsynaptic neurotoxins, antivenom may reverse this complication, but an anticholinesterase such as neostigmine may also cause a reduction in paralysis, although repeated doses will often be required, and this should not be used as an alternative to antivenom, but rather as adjunctive treatment, or where appropriate antivenom is unavailable (Grade III recommendation).

Myolysis

The major issues with myolysis often relate to secondary renal failure and hyperkalemia, which may cause lethal cardiac complications. In the early stages, before renal damage has occurred, an IV fluid load may help spare the kidneys. Alkalinization of urine has also been suggested, but it is unproven in this situation. It is uncertain whether early physical therapy speeds or hinders the muscle healing process. Experimentally, it takes about 4 weeks to recuperate from venom-induced myolysis, but it appears that only slow-twitch fibers recover, not fast-twitch fibers. This change in muscle makeup is unconfirmed in human victims of snakebite myolysis. The extent of muscle loss can be extreme and require a prolonged period of rehabilitation to rebuild normal muscle mass.

Coagulopathy and Hemorrhage

Management of coagulopathy generally takes place in the acute stage and is achieved by

neutralizing circulating procoagulant or anticoagulant with adequate antivenom, as discussed earlier. Replacement of depleted coagulation factors and fibrinogen with fresh frozen plasma or similar products while there is still active coagulopathy and circulating venom only adds fuel to the fire and increases fibrinolysis and therefore is rarely indicated. It should be performed only after it is clear that all procoagulants are neutralized, as shown by steady improvement in coagulation parameters, the exception being catastrophic bleeding (Grade III recommendation). In most patients, return to safe coagulation function (not normal function) will be sufficiently rapid, within a few hours, that the need for replacement therapy is obviated. In a few cases, return to safe levels may be too slow or reach a plateau or there may be major active bleeding. In such situations, replacement therapy is worth consideration. A study on Australian elapid bite coagulopathy giving FFP soon after antivenom found that if antivenom and FFP were given more than 6-h post-bite, then patients receiving FFP had recovery in laboratory coagulation parameters faster than those not receiving FFP, but this did not result in overall improved patient outcomes and for patients given antivenom, then FFP less than 6-h post-bite, outcomes were actually worse. The only fatality in this study was in the FFP study arm [39]. Some species, such as the Malayan pit viper, may cause prolonged coagulopathy, in part because of depot release of venom. Repeated doses of antivenom may be required.

Occasionally, the patient may recover from the immediate coagulopathy, only to move into a phase of thrombocytopenia with continued mild DIC. This complication, discussed earlier, is sometimes associated with renal failure where it may not be due to continuing envenoming, so further antivenom therapy is unlikely to be helpful. In other cases late developing thrombocytopenia without associated hemolysis or renal failure may be indicative of ongoing envenoming and may respond to further antivenom. This latter situation is particularly noted after North American rattlesnake envenoming where Fab antivenom, with a short half life, has been used rather than longer-lasting F(ab')₂ antivenom.

Some species may cause thrombocytopenia in the early phases of envenoming as a direct venom effect; antivenom is generally the most effective treatment.

Renal Failure

As discussed earlier, renal damage is most often secondary, although it may occasionally be primary, particularly with envenoming by snakes such as Russell's viper. Management will vary depending on the extent of damage. For a simple rise in creatinine and urea without significant oliguria or anuria, expectant treatment is often sufficient, with creatinine and urea usually showing slow improvement after 5–10 days. More severe renal failure, often associated with acute tubular necrosis at biopsy, may require a period of hemodialysis, but in most cases, normal renal function will eventually return. Rarely, more severe and permanent damage occurs, such as renal cortical necrosis, and requires continued renal support.

Local Necrosis

Conservative care is generally appropriate for local tissue injury to the bitten limb. It is unclear how effective antivenom will be in minimizing injury, but it should be given in most cases in the hope of at least reducing the extent of damage, if not eliminating it (Grade III recommendation). Secondary infection can occur but is not routine. Antibiotics should be used only when indicated and should be preceded by culture and sensitivity studies (Grade III recommendation). Fasciotomy to relieve local pressure is a much overused treatment in snakebite and frequently results in long-term functional deficits. It should be reserved only for cases in which significant compartment syndrome has occurred and been proved by intracompartmental pressure measurement (direct or Doppler) (Grade III recommendation). As noted earlier, at least for rattlesnake bites, there is a management algorithm for possible compartment syndrome [38]. Tetanus is a risk after snakebite, but to avoid serious hematomas, an immunization booster (IM) should not be given until after reversal of any coagulopathy.

Psychological Issues

Snakebite, even without envenoming, is often a severe psychological shock for the victim, especially children, and particularly if major envenoming has occurred and requires prolonged and extensive treatment. This issue should not be forgotten in the process of managing the patient's care.

Follow-Up

Patients who did not sustain significant envenoming and did not require antivenom will generally not require follow-up as long as they are carefully assessed before discharge and the discharge does not occur too soon after the bite.

Patients with significant envenoming requiring antivenom therapy should not go home until it is clear that the envenoming and its complications have resolved, a follow-up plan has been determined, and the patient is made fully aware of the symptoms of serum sickness and that this complication requires immediate review (Grade III recommendation). Follow-up should be arranged at approximately 1 and 2 weeks after discharge.

Special Populations

Preexisting illness may cause problems in some forms of snakebite. For instance, patients taking anticoagulants or antiplatelet drugs (even aspirin) may have a higher risk of bleeding if bitten by a snake with a venom causing coagulopathy or with a hemorrhagin-containing venom. Conversely, such medications will influence the interpretation of coagulation tests. Patients taking β -blockers, notably propranolol, may be less responsive to the epinephrine used to treat anaphylaxis [40, 41]. This has not been demonstrated to be a major issue in antivenom therapy, and the usual recommendation that antivenom be used only when clearly indicated applies. However, for patients receiving propranolol or similar medications, the need for antivenom therapy versus the risk of nonresponsive anaphylaxis should be

carefully considered (Grade III recommendation). This decision will entail a risk assessment specific for the individual patient, the type of snake, the probable degree of envenoming, and the efficacy and safety record of the chosen antivenom. Certain disease states may predispose to more severe envenoming or outcomes; renal diseases, cardiac diseases, and respiratory diseases are most prominent, but even a history of peptic ulcer may be relevant because it may increase the chance of major bleeding associated with venom-induced coagulopathy, as may liver disease associated with varices. These are but examples; for each patient, any preexisting disease or medication should be considered in relation to its interaction with the effects of the venom.

Pediatric Patients

In part because of their smaller body weight, children, especially young children, are at greater risk of severe or lethal envenoming. They may show more rapid deterioration. Conversely, despite their smaller mass, they should receive “adult” doses of antivenom, although dilution may need to be reduced to avoid fluid overload (Grade III recommendation). There may also be special problems in diagnosis in that a history may be unobtainable. Significant envenoming may result in an irritable or distraught child who may collapse or even have convulsions.

Pregnant Patients

In pregnancy, any venom-induced coagulopathy may result in bleeding affecting the fetus, and periods of hypotension may also damage the fetus. It is unclear which venom components may cross the placenta and directly affect the fetus, although most procoagulants have a large molecular weight and thus may not pass. Certainly, the health of the fetus should be closely monitored, but should major complications ensue, it may be necessary to sacrifice the fetus to save the mother. Surgical delivery should not be

contemplated in the presence of coagulopathy, except when it is the only remaining course of action to save the mother. It is unclear whether paralysis affecting the mother will affect the fetus, although it may not. Similar uncertainty surrounds myolysis. Antivenom should not be withheld because of pregnancy (Grade III recommendation).

Elderly Patients

The elderly and infirm are at greater potential risk from envenoming and should be managed with great caution and possibly more aggressive therapy.

In Africa, snakebites are neglected medical and surgical emergencies despite their high incidence and severity. Lacking mandatory reporting, in contrast to most Latin America and Asian countries, there is no official and consolidated epidemiological data. The main consequence is the lack of accurate assessment of therapeutic needs.

According to Chippaux [1], about 1 million snakebites occur every year in Africa involving 500,000 envenomings and about 20,000 deaths, although less than 10,000 are reported to health services. Kasturiratne et al. [2] estimated that 90,622–419,639 envenomings resulting in 3,529–32,117 deaths, excluding North Africa where around 1,500–40,000 snakebites and 20–40 deaths could occur, were reported every year. More recently, a new estimation by Chippaux [3], also based on medical literature, found that 314,078 [CI 95% = 251,513–377,462] envenomings were treated in modern health facilities, including 7,331 [CI 95% = 5,148–9,568] deaths and about 10,000 [CI 95% = 5,908–14,614] amputations. However, these figures reflect only part of the reality – probably less than half of the actual cases – because many victims do not reach the health center.

Although throughout Africa envenoming remains a public health problem, there is a strong epidemiological and clinical heterogeneity. This results from a wide variety of snake fauna, with very different behaviors and venom compositions, but also human activities mainly dependent on environmental and economic factors [4].

Finally, limited access to health centers and insufficient equipment and supplies limit the efficiency of snakebite management, leading to high mortality rates and complications.

The Snake Fauna

African snakes occupy all ecological environments, from desert to rainforest and high mountains, and all strata from the canopy to the subsoil and even the coast of Indian Ocean where a species of marine elapid (*Hydrophis platurus*) occurs.

The venom apparatus of snakes belong to four types [5]:

- The aglyphous lack fangs and are therefore unable to inoculate venom. Saliva may be toxic [6] and penetrate into the wound during a bite and generate clinical signs, usually locally; some of these snakes are now considered as “non-front-fanged colubrid (NFFC)” snakes.
- The opisthoglyphous, “non-front-fanged colubrid (NFFC)” snakes, have grooved teeth connected to a gland (Duvernoy’s gland) that produces venom in at least some species; they are located toward the rear of the mouth and may inject the venom into the flesh.
- The proteroglyphous possess few teeth that are also connected to a venom gland; grooved teeth are situated at the front of the maxilla; they are immobile and can inject the venom under pressure during the bite.
- Finally, the solenoglyphous have mobile teeth, very long and able to inoculate venom in depth and under pressure.

Of the 3,500 species of snakes in the world, nearly 500 live in Africa. The Scolecophidia, primitive burrowing snakes (over 50 species), are not dangerous to humans and are rarely encountered. The Henophidia, boas and pythons (ten species), can reach large sizes and sometimes inflict significant trauma because of their strong teeth, but they are not venomous. Only Caenophidia (recent snakes) have venomous species.

In Africa, Caenophidia are represented by four families (Table 1).

The Colubridae comprise less than a hundred species, most of them nonvenomous. However, two genera (*Thelotornis* and *Dispholidus*) are opisthoglyphous and may be responsible for severe envenoming [7]. Both are arboreal. The first genus inhabits the forest and extends from West Africa to East and Southern Africa. The second one lives in savannah from West Africa to East Africa.

The Lamprophiidae include somewhat less than 150 species, showing various types of dentition, including opisthoglyphous (e.g., *Psammophis*, a very common terrestrial genus, and *Crotaphopeltis* of which one species,

	<i>Proatheris</i>	Solenogl.	Hemorr. Necrot.	Terrestrial	East Africa

Hemorr. hemorrhagic; Inflamm. inflammatory; Neurotox neurotoxic; Cardiotox cardiotoxic

^aAlso known as *Boiga*

^bCurrently ranked among *Naja* genus

^cPreviously named *Pelamis*

C. hotamboeia, is ubiquitous and abundant even in towns) and a solenoglyphous snake genus, *Atractaspis*, or mole viper, consisting of burrowing species whose venom is necrotizing and cardiotoxic.

The Elapidae – 40 species – are all proteroglyphous and have a neurotoxic venom, sometimes necrotizing. These include *Naja* (cobra), which are terrestrial snakes exceptionally

arboreal or aquatic; *Dendroaspis* (mamba), all arboreal; and some rarer genera generally occupying the primary forest (*Pseudohaje*) or dry regions (*Elapsoidea* and *Aspidelaps*, both burrowing snakes found, respectively, in north of the equator and in Southern Africa).

Finally, the Viperidae (less than 50 species) are solenoglyphous. The venoms are inflammatory, hemorrhagic, and necrotizing. Most are terrestrial

(*Bitis*, *Echis*), but some genera are more or less burrowing (*Causus*, *Cerastes*) or arboreal (*Atheris*).

The snakes are territorial, and their home range is limited to a few hundred square meters for species whose biomass is low and can reach several hectares for large species like *Python sebae*, a nonvenomous python (Pythonidae), or *Bitis arietans*, a very venomous viperid (Viperidae) whose adult weight exceeds 5 kg and the litters range between 25 and 40 [5]. The home range of pregnant females is further reduced, sometimes to a few m². The ecological environment influences the extent of the home range, depending on food production: it is often larger in savannah than in forest, for snakes of equal size.

In tropical countries, particularly those where the dry season is long and rough, reproduction is generally seasonal, leading to birthing at the beginning of the rainy season [8]. This optimizes the chances of survival of juveniles. However, predation is high, and in the equatorial areas, for example, over 90% of the snakes born in the year disappear [9]. Among the predators, humans are probably the most important, either for economic reasons (bush meat or leather) or accidentally, especially by crushing on roads or because of the use of agricultural insecticides toxic for reptiles [10, 11].

Snakes live hidden and exit hiding in three main circumstances, unless they are disturbed, the latter influencing the encounter with a human, especially if the habitat of the snake occurs in a place where humans cultivate or inhabit. The main stimuli that induce the snake out of hiding are hunting, mating, and giving birth (or laying eggs, dependent on species). Snakes feed at a rate that varies from one to several weeks, depending on the size of the previous meal, opportunities, and physiological needs. They seek prey either through ambush predation (e.g., a puff adder, *Bitis arietans*, positioning itself near an animal movement pathway) or through active hunting of prey (e.g., mambas, *Dendroaspis* spp., actively searching out prey) depending on species. The mating is seasonal in most species [12]. The male looking for a female to mate with may move widely during long trips

that increase the apparent abundance of snakes by a factor of 5–7 [9]. Finally, the timing of births – birth for oviparous snakes and farrowing for ovoviviparous – increases temporarily the demography and is manifested by a greater flow of young snakes in search of their new territory.

While many species disappear because of the human impact on the environment, including urbanization, some others are likely to adapt to environmental changes. This has been observed even in a few venomous snakes – like *Echis ocellatus* or *Naja melanoleuca* – in cities [3, 12]. However, the most significant phenomenon is the abundance and composition of ophidians living in large industrial plantations. The special habitats created by this type of plantation determine a selective environment that allows certain species to find favorable conditions for their development [13–17]. The risk for the workers of these plantations depends on the species attracted to these artificial biotopes, e.g., western green mamba (*Dendroaspis viridis*) in rubber plantations or rhinoceros viper (*Bitis nasicornis*) in cocoa farms [13, 18].

Selected African Venomous Snakes

Carpet or Saw-Scaled Vipers: Genus *Echis*

Arguably the medically most important snakes in African savannahs, carpet vipers have a wide distribution from West Africa across to the Middle East (and beyond as far as Sri Lanka). Though small, with small fangs and venom which is not technically as potent as some other snakes, the effects of this venom on humans can be devastating and the high frequency of bites by these snakes, which have thrived in agricultural and even urban areas, ensures their medical importance. There is significant venom variability across species which complicates choice of anti-venom. Bites cause both moderate to severe local effects (pain, swelling, blistering, bruising, bleeding, necrosis, fluid shifts into the bitten limb resulting in hypovolemic shock) and potentially lethal systemic effects including coagulopathy (defibrination), anemia, and less commonly thrombocytopenia, with renal failure

occasionally. Fatality is usually associated with the severe hemorrhagic coagulopathy.

Classic African Vipers: Genus *Bitis*

There are numerous *Bitis* species and they do not all share similar clinical effects. The most medically important species, the puff adder, *B. arietans*, causes moderate to severe local effects (pain, swelling, blistering, bruising, bleeding, necrosis which can be extensive, fluid shifts into the bitten limb resulting in hypovolemic shock), but major systemic effects (other than secondary shock and cardiac compromise) are not prominent and despite the local bleeding, systemic coagulopathy is not usually a feature, though thrombocytopenia does occur. Death is usually due to shock or cardiac compromise. The closely related Gaboon viper, *B. gabonica*, and rhinoceros viper, *B. nasicornis*, causes clinical effects similar to puff adders, except that they are also associated with hemorrhagic coagulopathy, plus early autopharmacologic collapse. In contrast, some other *Bitis* spp. cause predominantly systemic effects, notably the berg adder, *B. atropos*, which can cause flaccid paralysis in addition to local pain and swelling, but without necrosis or systemic coagulopathy.

Horned Desert Vipers: Genus *Cerastes* (Fig. 1)

These North African desert-dwelling snakes mostly cause local effects (pain, swelling,

blistering, bruising, necrosis (uncommon), potentially fluid shifts into the bitten limb resulting in hypovolemic shock), with secondary systemic effects (shock, cardiac compromise), but there are reported cases with severe coagulopathy, hemorrhage, microangiopathic hemolytic anemia, and secondary renal failure, and they can cause fatalities. As with *Echis*, there is significant venom variability across their geographic range and species, with consequent issues in selecting antivenom.

Night Adders: Genus *Causus*

Night adders are a common cause of snakebite in sub-Saharan Africa and can cause local pain and large swelling and regional lymphadenopathy, but not necrosis or major systemic effects, and fatality is not reported. No antivenom is available although there is a good paraspecificity of African polyvalent antivenoms.

Bush Vipers: Genera *Atheris*, *Protoatheris*, and *Montatheris*

In Africa there is little clinical data on these snakes and so bites are assumed to be uncommon to rare, but they are popular outside Africa as captive snakes, and at least one species, *A. squamiger*, has caused a fatality. Bites cause both local effects (pain, swelling which may be severe, bruising, not necrosis) and severe systemic hemorrhagic coagulopathy which can persist for days and is potentially fatal. They can also cause shock and renal failure. There is no antivenom available.

Fig. 1 *Cerastes gasperettii*
(Photo courtesy of Julian White)

Eurasian Vipers: Genera *Macrovipera* and *Vipera*

These classic vipers are represented in Africa by *M. lebetina*, *M. mauritanica* and *V. monticola*, all found in North Africa. From limited clinical data, it appears *M. lebetina* can cause moderate to severe local effects (pain, swelling, blistering, necrosis, fluid shifts into the bitten limb resulting in hypovolemic shock), while systemically there can be coagulopathy, bleeding, anemia, hemolysis, thrombocytopenia, and possibly renal failure, and an older report claims a 50% fatality rate, though this is certainly too high. There is no corresponding information on bites by *M. mauritanica* or *V. monticola*, which could be assumed to be similar to *M. lebetina*.

Other African Vipers: Genera *Pseudocerastes* and *Adenorhinos*

There is minimal clinical data for the false horned viper, *Pseudocerastes persicus*, but based on this, it appears likely to cause on mild to moderate local effects, without systemic effects of consequence. Despite this apparent lack of clinical significance, there is an antivenom available (Iran) that includes *P. persicus* venom in the immunizing mix. There is no case data for *Adenorhinos barbouri* bites, though it has been compared to small *Atheris* spp. and might be expected to cause only mild to moderate local effects. There is no antivenom available for this snake.

Cobras: Genera *Naja*, *Hemachatus*, *Walterinnesia*, and *Pseudohaje*

The cobras represent the most medically important elapid snake group throughout Africa. In the dominant genus, *Naja*, typical cobras (and now including the water cobra, *Naja (Boulengerina) annulata*) are the most common and important and may be divided clinically into the spitting and non-spitting cobras. Spitting cobras within genus *Naja* have modified fangs and associated venom delivery apparatus, allowing them to defensively spit a dual tightly fanned stream of venom up to 2–3 m, generally aiming for their opponent's eyes. Upon contact with the eyes, the venom causes intense pain and can damage the cornea unless promptly washed. Systemic

envenoming from venom spit is not expected. In general spitting cobras have locally active venom that causes ulceration and/or necrosis around the bite site, with only nonspecific systemic effects. If there is major tissue damage in the bitten limb, there may be secondary fluid shifts resulting in shock, and its sequelae and secondary infection and long-term scarring are common. Though neurotoxic (postsynaptic only) flaccid paralysis may occur, it appears generally uncommon and usually not severe, for most spitting cobra species. In contrast, the non-spitting cobras include a number of species that cause relatively mild local reactions, but do cause sometimes severe, even lethal, neurotoxic paralysis, and the latter may sometimes develop rapidly as classic descending flaccid paralysis, usually first seen as ptosis, an important early warning sign. There is clinical data on bites by only some of these cobra species. In some local pain and swelling may be significant, but without necrosis. Regional lymphadenopathy is reported. Several antivenoms are available covering some species, but it is unclear if there is sufficient cross-reactivity to assuredly treat envenoming by some of the other species, especially the rarer species. African cobras are not reported to cause rhabdomyolysis and, in general, seem not to cause coagulopathy, although there are limited reports for a few species such as the black spitting cobra, *N. nigricincta*, suggesting it may cause at least laboratory-detectable coagulation anomalies, though possibly not clinical bleeding. Though cobra venom contains "cardiotoxins," cardiotoxicity is not clinically described, and a recent report of takotsubo cardiomyopathy following a Cape cobra, *Naja nivea*, bite concluded this was not a direct envenoming effect, but rather related to anxiety-mediated catecholamine release [19]. Despite being locally common, the red-necked spitting cobra, *Hemachatus haemachatus*, has limited published clinical data. From this it appears to typically cause local pain, swelling, and ecchymosis, but blistering and necrosis are rare, and while fatalities due to neurotoxic respiratory paralysis are recorded, major paralysis appears to be uncommon to rare. This species is covered within a polyvalent antivenom. The black desert cobra,

Walterinnesia aegyptia, appears to be an uncommon cause of bites and generally causes predominantly local effects (pain, swelling, but not blistering or necrosis) and nonspecific systemic effects, but does not appear to cause paralysis, coagulopathy, or rhabdomyolysis, based on current limited clinical data. It is covered by several North African/Middle East polyvalent antivenoms. There is essentially no information on bites by tree cobras, *Pseudohaje* spp., and it is presumed they are a rare and inconsequential cause of bites, without any apparent need for or availability of specific antivenom. Similar comments apply to the burrowing cobra, *Naja* (formerly *Paranaja*) *multifasciata*.

Mambas: Genus *Dendroaspis*

The mambas; the three green mamba species, *Dendroaspis angusticeps*, *D. jamesoni*, and *D. viridis*; and the black mamba, *D. polylepis*, are among the most feared African venomous snakes, especially the black mamba. As discussed elsewhere in this chapter (under venoms), these snakes possess unique neurotoxins which work synergistically at the neuromuscular junction (NMJ) to cause both muscle fasciculation and paralysis. Bites may cause significant local pain and swelling and for the green mamba species, occasionally local necrosis, plus often severe abdominal pain and rapid onset of neurotoxicity, the latter especially following black mamba bites. Neurotoxicity may develop within 15 min or be delayed many hours. There may also be autonomic effects and increased sweating and salivation. Antivenom is available and raised against the black mamba.

Other African Elapids: Genera *Aspidelaps* and *Elapsoidea*

Shield nose snakes, *Aspidelaps* spp., appear to be a rare cause of bites, but the limited clinical data indicates they can cause neurotoxic flaccid paralysis, with at least one fatal case reported. Local effects may include pain, swelling, and regional lymphadenopathy, but not blistering or necrosis. There is no current evidence they cause coagulopathy, though the venom has procoagulant activity. No antivenom is available.

There is virtually no clinical data on African garter snakes, *Elapsoidea* spp., but this very limited information indicates bites are rare and cause no more than local effects (pain, swelling, regional lymphadenopathy), with no fatalities recorded. No antivenom is available.

African Atractaspine Snakes: Genera

Atractaspis* and *Homoroselaps

The side-fanged and burrowing snakes, family Lamprophiidae and subfamily Atractaspinae, are a significant cause of bites in Africa, particularly the mole vipers, *Atractaspis* spp., at least some of which have caused fatalities. These snakes are adapted to a subterranean existence including sideswiping their prey with the fang which can be protruded from the side of the mouth. This latter positioning makes these snakes difficult to safely hold behind the head, compared to other venomous snakes. At least some (notably *A. engaddensis*) have unique endothelin-mimicking cardiotoxins and sarafotoxins that can cause myocardial ischemia, infarction, and cardiac arrhythmias. However, the majority of patients bitten by *Atractaspis* spp. develop predominantly local (pain, swelling, blistering, sometimes necrosis, painful regional lymphadenopathy) and nonspecific systemic effects (headache, nausea, vomiting, diarrhea, fever, nonspecific weakness), rather than cardiotoxicity. At least two species (*A. corpulenta*, *A. engaddensis*) have caused coagulation abnormalities, but it is unclear if this is a primary venom effect or secondary. Bites by harlequin snakes, *Homoroselaps* spp., appear to be rare and are associated with mild, occasionally severe local pain and swelling, with local bleeding reported, but not necrosis or cardiotoxicity, based on current limited clinical data. There is no antivenom available for these snakes.

Major African Non-front-fanged Colubrids (NFFCs): Genera *Dispholidus*, *Thelotornis*, *Malpolon*, *Psammophis*, and *Toxicodryas*

The boomslang, *Dispholidus typus*, is a widespread arboreal “rear-fanged” snake, family Colubridae (Colubrinae), which has caused a

number of fatalities due to severe coagulopathy. The bite may cause minimal pain and swelling, but severe defibrination coagulopathy with active bleeding (hematemesis, hematuria, melena, widespread ecchymosis, intracranial hemorrhage) can develop over subsequent hours in addition to nonspecific systemic effects (headache, nausea, vomiting, abdominal pain), and there is a risk of microangiopathic hemolytic anemia and secondary renal failure. A specific antivenom is available from South Africa. Vine or twig snakes, *Thelotornis* spp., also arboreal, can cause similar clinical effects to the boomslang, with fatalities recorded, but there is no effective antivenom available. The Montpellier snake, *Malpolon monspessulanus* (family Lamprophiidae, subfamily Psammophiinae), is a “rear-fanged colubrid” (NFFC) snake with an uncertain clinical record and significance. It has been reported to cause difficulty with swallowing and respiration, which was presumed to indicate neurotoxicity, but this has not been confirmed with either venom studies or further cases documenting paralytic features. Bites cause mild to moderate local pain and swelling, without blistering or necrosis. *M. monspessulanus* is found only in the north-western part of Africa (West of Maghreb), but a close species, *M. moilensis*, is present in all the Sahelian area of north and sub-Saharan Africa. No antivenom is available. *Psammophis* sp., belonging to the same subfamily, is the most current NFFC in whole Africa. Bites are frequent but generally with no or mild clinical effects, i.e., limited pain and swelling. *Toxicodryas*, closely related to Asian *Boiga*, are arboreal. *T. blandingii* bite may cause mild neurotoxic effects (myalgia, cramps, and sensitivity troubles; [20].

There are many other NFFC snakes in Africa for which there is either limited or no clinical data and, in many cases, not even venom data. It is conceivable that some of these species might, occasionally, have a capacity to cause at least mild to moderate non-necrotic local envenoming. Given the lack of clinical data, all bites by captive specimens where the identity is assured should be reported, even if no detectable clinical effects occur. Given that NFFC species previously

considered “harmless” have subsequently caused lethal envenoming, usually due to coagulopathy, it may be prudent to manage bites by all these species with some suspicion and test for coagulopathy.

Venom Composition

Snake venom consists of a mixture of numerous substances (toxins) including many proteins, either low molecular weight peptides or high molecular weight enzymes. Peptides and enzymes bind their target with high specificity, which does not prevent the redundancy, potentiation, or competition between multiple components present in the same venom.

The main toxins found in African snake venoms are neurotoxins from elapids, sarafotoxins in *Atractaspis* venom, and disintegrins and other toxins acting on hemostasis, found in viper venoms. However, the old view that vipers cause bleeding and local necrosis and elapids cause paralysis is an inaccurate oversimplification. Some elapids, indeed many African species, may cause significant local tissue injury, and this may be more important than neurotoxicity.

All African Elapidae have a neurotoxin- α (curare-like or three-finger toxin) whose molecular weight is 7 or 8 kDa, and the number of amino acids ranges between 60 and 74 with four disulfide bridges [21]. In addition to this neurotoxin- α (α -bungarotoxin-like), mambas (*Dendroaspis*) have three other types of neurotoxin, muscarinic toxin, fasciculin, and dendrotoxin, whose molecular weight is 6–7 kDa (57–65 amino acids and three disulfide bonds). Their structure is very similar to neurotoxin- α , but they bind to other neuroreceptors resulting in other clinical effects. Binding of the neurotoxins to their receptor may be irreversible, resulting in a direct proportionality between the amount of injected toxin and the effect it causes.

The sarafotoxins of *Atractaspis* contain 20 amino acids and two disulfide bridges totalling 2.5 kDa. They are cardiotoxic, are homologous to mammalian endothelins, and possess similar pharmacological properties [22].

The disintegrins are peptides of 5–15 kDa, i.e., 49–84 amino acids with four to eight disulfide bridges [23], depending on whether they are monomeric (*Echis ocellatus*) or polymeric (*Bitis arietans*).

Among the enzymes observed in African snake venoms, the most frequent are phospholipases, acetylcholinesterase, proteases, and some others of lesser importance (L-amino acid oxidase whose role is unknown and hyaluronidase supposed to facilitate the spread of venom).

Phospholipases A₂ (PLA₂) may be in the form of a monomer (8 kDa) or a polymer (36 kDa). They hydrolyze soluble phospholipids present in the plasma and cell membrane phospholipids, although some PLA₂-derived toxins have little or no residual antiphospholipid activity. Phospholipases active on the presynaptic membrane, also known as β -neurotoxin (β -bungarotoxin-like), have not been isolated from African snake venom.

The mamba fasciculins, acetylcholinesterases (126 kDa), degrade acetylcholine.

Proteinases (20–100 kDa) are classified into two structural groups: serine proteinases that use serine to bind to their substrate [24], which includes thrombin-like enzymes [25], and metalloproteinases, characterized by the presence of an ion in their structure, usually zinc, acting according to their size, on fibrinogen, fibrin, or the vascular endothelia [26]. Initially, these enzymes activate clotting by forming a generally incomplete or unstable clot. The consumption of coagulation factors explains afibrinogenemia and the lack of blood coagulability.

Pathophysiology of Envenoming

Toxins diffuse rapidly throughout the body and bind specifically to cellular receptors causing disruptions. Their clearance may take several days or weeks. They are considered as dose dependent. Enzymes diffuse more slowly and transform their substrate molecule in 1/1000th per second until the exhaustion of the substrate. Although the inoculated dose plays a major role, a low concentration can produce significant effects before the release of the enzyme that takes several days: they are chrono-dependent.

Inflammatory Action

The enzymes of snake venoms, especially those from Viperidae, are responsible for the intense inflammatory process that is observed in most of ophidian envenoming.

Phospholipases A₂ release arachidonic acid, a precursor of inflammatory substances, such as leukotrienes, which increase capillary permeability, and prostaglandins that activate bradykinin and thromboxanes, which increase the vasodilatation and extravasation, resulting in hypotension and edema [27]. In addition, the release of inflammatory cytokines will also stimulate the nonspecific defense mechanisms [28].

Proteases, particularly metalloproteinases, destroy the vascular endothelium causing bleeding and accentuating the inflammatory response [29].

Action on the Nervous System

The specificity of the different α -neurotoxins explains the pharmacological and clinical features [30]. Neurotoxins from elapid venoms block the transmission of nerve impulses specifically at the neuromuscular junction (NMJ), either presynaptically (β -neurotoxins; β -bungarotoxin-like) or postsynaptically (α -neurotoxins; α -bungarotoxin-like). Not all elapids have both types of toxin, and African elapids (cobras specifically) appear to possess just α -neurotoxins that bind to (or adjacent to) the nicotinic acetylcholine receptor on the muscle end plate at the NMJ, thereby preventing binding of acetylcholine and thus blocking neurotransmission, resulting in curare-like descending flaccid paralysis. Clinically this is first manifest in cranial nerves (ptosis, then partial, becoming complete ophthalmoplegia, loss of facial expression, open mouth, drooling, fixed dilated pupils, loss of upper airway protection) and extends to all the skeletal motor muscles, including the intercostal muscles and the diaphragm. Dendrotoxins found in mamba snake venom, while also targeting the NMJ, block the voltage-gated potassium channels of the presynaptic membrane, increasing acetylcholine release.

The fasciculins inhibit acetylcholinesterase, the role of which is to regulate the transmission of nerve impulses by degrading acetylcholine after its action on the postsynaptic receptor. The synergistic actions of dendrotoxins plus fasciculins result in massive oversupply of neurotransmitter at the NMJ, with muscle fasciculation and paralysis. The muscarinic toxins bind to the M₁ acetylcholine receptors of the postsynaptic membrane possessing a highly excitatory activity on the parasympathetic system [31].

Actions on Blood Coagulation

Bleeding is related to the action of several factors [32].

Locally – and sometimes far from the bite – the hemorrhagins, which are metalloproteinases, perforate the vascular endothelium and cause local bleeding and extravasation of the blood from the vascular compartment. This phase is very fast and essentially mechanical [29].

Other metalloproteinases, such as ecarin present in the venom of saw-scaled vipers (*Echis* sp.), are activators of prothrombin. They hydrolyze the latter to form meizothrombin [33] resulting in fibrin formation, the skeleton of the blood clot, with simultaneous activation of fibrinolysis, resulting in rapid and devastating consumption of circulating fibrinogen.

Thrombin-like enzymes are very common in Viperidae. They hydrolyze the fibrinogen, releasing fibrinopeptides A and/or B, allowing the formation of fibrin [32]. However, the role of these components in African viperid snakebite is less clear.

Finally, there are several enzymes acting on platelets, activating or inhibiting platelet aggregation [34]. The cerastobin, cerastocytin, and cerastatin, for example, are serine proteinases isolated from the venom of *Cerastes cerastes*, a North African viperid. They show both thrombin-like and platelet-aggregating properties but act at different levels of the blood coagulation pathway and platelet function.

Mambin and dendroaspin, found in the venom of *Dendroaspis*, are proteins showing the same

general structure as the three-finger toxins. However, they do not act on neuromuscular transmission but inhibit platelet aggregation [35, 36].

The activation of coagulation pathways, resulting from the action of most components of vipers and some colubrid venoms, causes the consumption of plasma coagulation factors making the blood unclottable (afibrinemia, afibrinogenemia, thrombocytopenia, etc.).

In Africa, vascular thrombosis and visceral infarctions are uncommon during the procoagulant phase, i.e., at the beginning of envenoming. However, it has been described, especially after *Echis ocellatus* and more often after *Cerastes cerastes* envenoming as either cardiac infarctions [37] or ischemic strokes [38–40].

Various Actions

The sarafotoxins from some *Atractaspis* sp. are cardiotoxic. They cause coronary vasoconstriction and cardiac ischemia [41].

Various proteolytic enzymes are responsible for tissue destruction, causing a more or less extensive necrosis [42], which can be amplified by a secondary anoxia, resulting from the edema or iatrogenic complications after placing a tourniquet, for example, or superinfections following traditional treatment [43, 44].

Epidemiology of Envenoming

In tropical Africa, snakebites are highly underestimated [1, 3]. Several reasons explain the underreporting. Snakebites are attributed to supernatural and not casual or medical reasons, punishment, revenge, spell, witchcraft, etc., which require the intervention of a traditional healer to lift the curse. Over 90% of victims consult a traditional healer at first instance, and between 40% and 60% do not attend hospital, either because it's too late or because they do not trust modern medicine [3, 45–48]. The accessibility of health facilities is poor, equipment and drug supplies are low, and availability and training of health personnel are insufficient. Data collection

and reporting systems are inefficient or nonexistent, which limits epidemiological assessments. In addition, antivenom is expensive, often difficult to preserve in remote health centers, and its administration remains poorly codified [49, 50]. However, a better assessment of the incidence and morbidity is essential for improving care. It would help to provide appropriate amounts of antivenom and determine their positioning for rational use [51].

The economic evaluation of the cost of snakebites is not yet a common practice. It is necessary to take into account the patient's disability time during the treatment, the cost of the latter, and the complications of the envenoming, either the patient's death or disability resulting from necrosis or surgical treatment. Long-term or permanent disability can be measured by the disability-adjusted life years (DALYs).

Available data are incomplete and come from two sources [3, 52]:

- The records of health centers (more or less well kept) lead to an estimation of 300,000 envenomings and nearly 10,000 deaths a year in sub-Saharan Africa.
- The community surveys suggest that there are two to three times more cases (1 million per year) and three to four times more deaths (about 30,000 per year).

Three quarters of the bites occur during agricultural work, hunting, or movement related to work [3]. The agriculture practiced using traditional methods leads to high exposure, which is strengthened by the attraction of snakes to agribusiness plantations where human activity is intense (see section “[The Snake Fauna](#)”).

Young men undergo between 50% and 75% of bites. Children, although they represent almost half of the general population, are bitten less often than might be expected, similarly women, the latter contributing to agricultural work as much as men.

The seasonal incidence of accidents is related to the behavior of snakes and the agricultural agenda, both related to the climate. Geographical variations are largely dependent on agricultural

practices: in forest regions, bites are more spread out throughout the year, while in the savannah, snakebites are more frequent during the rainy season. The relationship with rainfall reflects its close involvement in both behavior of ophidians and human activities.

A majority of snakebites occur in late afternoon or early evening. Some occur at night and occur while the human is sleeping, bitten by snakes searching for food inside houses.

Over 80% of the bites are located on the lower limb, especially below the knee, but significant geographical variations are observed. Bites to the hand are uncommon to rare, but not exceptional, especially among farmers who work with tools with a short handle or in children who dig with bare hands in burrows in search of small vertebrates to supplement their diet [53].

Finally the main factors that influence the incidence are [3]:

- Annual rainfall exceeding 500 mm
- A population density below 100 inhabitants per km²
- A dominant agricultural activity, some types of cultivation associated with an increased incidence, and/or severity of bites, like cotton or sugar cane plantations where *Echis ocellatus* and *Bitis arietans* are particularly abundant

Clinical Presentation of Envenoming

The severity of bites is influenced by several factors [3, 50, 54]. The toxicity of the venom and the amount injected by the snake are obviously important factors. They depend on the snake species, its size, capacity of its venom glands and current content, and circumstances of the bite. Multiple bites are more likely to result in major envenoming. The age, size, health status of the victim, and the location of the bite are also important. The time to use first aid or nonmedical treatment and the type of first aid or other nonmedical treatment are important as many nonmedical treatments are either ineffective or actually cause harm and may even speed envenoming. Finally, the time between the bite and effective treatment

will also have major consequences. Delayed treatment may induce complications and reduce the effectiveness of treatment. As a result, this is one of the main factors predicting mortality after envenoming [54].

The frequency of asymptomatic bites, i.e., inflicted by nonvenomous snakes or venomous ones not injecting their venom (“dry bites”), is on average 40% in savannah and 60% in forest where they can reach 80% in some countries [1, 3, 50, 55].

At least four envenoming syndromes can be described. Presentation may involve more than one syndrome and this can complicate diagnosis and treatment.

Inflammatory Syndrome

It consists of severe pain, a more or less extensive edema, sometimes fever and leukocytosis higher than 10,000 leukocytes per mm^3 . Development is generally rapid and lasts for 2–5 days. Edema decreases slowly (1–3 weeks), even with treatment by antivenom.

If significant edema appears, it is necessary to look for distal signs of cyanosis and perform, if possible, an ultrasound and measure the intracompartmental pressure [53, 56]. Surgical intervention for compartment syndrome (fasciotomy) should never be performed unless true pathological raised intracompartment pressure has been confirmed by appropriate measurement (see later).

Hemorrhagic Syndrome

It manifests with local and or systemic bleeding (Fig. 2).

Bleeding from the fang marks appears immediately after the bite. It can persist for several days or even a week or two, resulting in anemia that can be severe (hemoglobin below $5 \text{ g} \cdot \text{dL}^{-1}$). Remote bleeding (gums, nose, old scars) or cutaneous manifestations (purpura, blisters) usually begin 30 min to 3 h after the bite, but can be delayed for 2 or 3 days when the amount of venom injected is minimal. Internal bleeding should be

Fig. 2 Hemorrhagic syndrome after *Echis ocellatus* bite. Note the blood tears whereas the child was bitten on the left foot (Photo courtesy of Jordan Benjamin)

considered clinically and, if possible, determined using imaging such as an ultrasound. Meningeal or peritoneal hemorrhage and extensive bruising are the most frequent manifestations.

Hematology and coagulation tests are very useful but often not feasible due to the lack of an effective functional laboratory in the African setting. However, it is always possible to perform a whole blood clotting test (20WBCT) in a clean dry glass tube or vessel, even in the peripheral health centers (Fig. 3). The global standard test is the 20WBCT, described subsequently in this chapter.

Neurological Syndrome

This commences with sensory disturbances, initially locally (anesthesia, tingling) and then central (tinnitus, blurred vision, diplopia, dysgeusia) accompanied by a descending flaccid motor paralysis, ptosis, dysphonia, dysphagia, and dyspnea, and then limb weakness progressing to respiratory paralysis causing asphyxia and death if not treated

Fig. 3 Whole blood coagulation test

Fig. 4 Neurotoxic syndrome after *Naja melanoleuca* bite. Note the typical ptosis and rictus (Photo courtesy of Cellou M. Baldé, IRBAG, Kindia, Guinea)

(Fig. 4). In Africa this is associated with bites by some elapid snakes.

Dendroaspis venoms, besides the neurotoxic syndrome described above, are responsible for a hypersecretory syndrome (= muscarinic syndrome). Soon after the bite, the patient shows sialorrhea, excessive perspiration, vomiting, diarrhea, abdominal pain, and miosis (Fig. 5). Further, the synergistic actions of dendrotoxins (cause excess presynaptic release of acetylcholine) and fasciculins (anticholinesterases blocking normal removal of excess acetylcholine from the synaptic cleft) result in atypical neurotoxicity, with muscle fasciculation in addition to paralysis.

Necrosis

Necrosis can appear quickly after the bite. It is usually dry but can become secondarily infected and purulent (Fig. 6). It extends slowly stabilizing in about a week, unless a secondary gangrene develops and complicates the evolution (Fig. 7). It may also develop in the areas of initial blistering and bleb formation, though not all cases with such an initial local reaction will progress to skin necrosis.

Diagnosis of Envenoming

The diagnosis is mainly clinical. The lack of laboratory facilities in most African health facilities severely limits the biological confirmation of the envenoming, etiologic diagnosis of hemorrhagic syndrome, and prevention of complications, including kidney failure.

History should include specific circumstances and time of the bite, the description of the snake, and treatments taken before arrival in hospital, plus past medical history including any previous snakebites or exposure to antivenom.

The examination evaluates for fang marks, checks for multiple bites, and determines the size and grade of the edema (Table 2). Presence and depth of necrosis should be determined and specified. Check draining lymph nodes for enlargement and/or tenderness, potentially indicating venom absorption and movement.

The location and size of bleeding are estimated and graded (Table 3). The 20WBCT is performed in all cases of bite showing an inflammatory syndrome and, a fortiori, hemorrhagic syndrome.

Neurological disorders are evaluated in detail and are also subject to severity grading (Table 4).

These evaluations and gradations are important in assessing the severity of envenoming, decision on (the dose of) antivenom, and monitoring the clinical course of envenoming.

Note that the use of a grading system to evaluate any aspect of envenoming is controversial and not universally accepted. Grading is also limited by the timing of assessment, and because

snakebite envenoming is generally a progressive disease, it is important to frequently reassess the grading level, to detect change that might require a different level of therapeutic intervention. Irrespective of grading, some clinical common sense is required to assess the overall patient and the impact of envenoming, including the contribution of preexisting disease and therapy. Because of their smaller body mass, children are potentially more likely to suffer severe envenoming and may progress from minimal effects to major envenoming more rapidly.

In rural Africa, ultrasound examinations are rarely possible although they could facilitate diagnoses of internal bleeding. Measuring intracompartmental pressures is essential for accurate diagnosis of compartment syndrome which can complicate a significant edema and indicate a need for surgical treatment such as fasciotomy [56].

Whenever possible, a complete blood count should be performed to evaluate for anemia and leukocytosis, which are useful in assessing the severity and evolution of hemorrhagic and inflammatory syndromes, respectively. Platelet counts, prothrombin time, fibrinogen, and D-dimer levels that allow monitoring therapy for hemorrhagic syndrome should be performed, if available, and repeated to monitor for change. The presence of thrombocytopenia highlights the effect of disintegrins. Creatine phosphokinase (CPK; CK) levels higher than 5,000 U/L may be a good

Fig. 5 Muscarinic syndrome after *Dendroaspis polylepis* bite. In addition to the neurotoxic syndrome, note the hypersecretion syndrome (Photo courtesy of Cellou M. Baldé, IRBAG, Kindia, Guinea)

Table 2 Clinical gradation of edema

Grade	Symptoms
1	Localized edema reaching the nearest joint
2	Progressive edema not exceeding two joints
3	Extensive edema not exceeding the limb
4	Edema beyond the root of the limb (anasarca)

Table 3 Gradation of bleedings and hemorrhages

Grade	Symptoms
1	Persistent local bleeding over an hour
2	Bleeding from the mouth, nose, or scars
3	Hematoma, ecchymosis, purpura, blisters
4	Internal hemorrhages (peritoneal, meningeal, etc.)

Table 4 Clinical gradation of neurological disorders

Grade	Symptoms
1	Anesthesia, tingling, local pins, and needles
2	Sweat and abundant saliva, vomiting, miosis
3	Ptosis, troubles of vision, hearing, and swallowing
4	Respiratory distress, impairment of communication

indicator of the extent of necrosis, allowing monitoring of the subsequent action of the proteolytic enzymes on the myolysis. Note that direct venom-induced rhabdomyolysis, a risk with snakebites in

some other parts of the world, has not been reported as a risk with African snakebite, at least so far. Very high CK levels should raise suspicion of systemic rhabdomyolysis which might require muscle biopsy for confirmation (only consider once any coagulopathy has fully reversed). Renal involvement is detected by maintaining good fluid balance charts (looking for polyuria, oliguria, or anuria) and the measurement of creatinine and urea levels.

However in the absence of laboratory, it is always possible to perform a whole blood clotting test (20WBCT) (Fig. 3).

Treatment of Envenoming

The management of snakebites raises two types of issues: firstly, antivenom supply and, secondly, training of health personnel. In fact, when both factors are resolved, victims quickly attend health centers, and the mortality is reduced by a factor of five to tenfold [57].

Ineffective management due to the lack of health structures, or appropriate equipment and medication, as is common in many African countries, increases the risk of poor outcomes whatever the time between the bite and treatment. First aid, when aggressive – tourniquet, incisions, scars, traditional poultice – may worsen the

envenoming. Superinfection, for example, aggravates the local lesions and causes disabling sequelae.

Any snakebite requires thorough washing of the wound and ensuring that tetanus immunity is up to date [58]. However, it is important to avoid injections while there is active coagulopathy.

In case of severe wound damage or infections, local treatment using Dakin's solution (boiled water with sodium hypochlorite solution 0.5% + sodium permanganate 100 mg · L⁻¹) is repeated twice a day, at the same time that evacuation of lesions is performed to assess the clinical evolution. Where possible, standard culture and sensitivity testing should be performed to allow targeted antimicrobial therapy, if clinically indicated.

Specific Treatment: Antivenom Immunotherapy

The antivenom must meet precise specifications of efficiency, i.e., manufacture using immunizing venoms from the relevant species and geographic area, and production methodology including removal of contaminants [59, 60]. Its price must be affordable and distribution correspond to epidemiological needs to supply the peripheral health centers, among others. This requires a functional and efficient notification system to identify the locations where antivenoms should be positioned. Competition among producers may be a theoretical price control factor, but the reality in Africa is that the range and supply quantity of antivenoms are inadequate, so such competition is unlikely. Complementary financing schemes (insurance, equalization, partial support by the national or local governments, private companies, and orphan drug policy) should be adapted in each country. Furthermore, the problem of product preservation must be resolved either by an appropriate cold chain or the lyophilization of the antivenom to reduce the risk of protein degradation and facilitate inventory management [49, 50]. However, lyophilization is a delicate process and requires that the solubilization of the antivenom can be obtained in less than 5 min, which is uncommon [61, 62].

The cost-effectiveness of antivenom was evaluated by comparing the evolution of snakebites between patients treated with or without antivenom [63]. A decision-analytic model was developed and tested using the following variables: species of snakes causing the bite, effectiveness of antivenom, case fatality rate in the absence of treatment, risk of adverse reactions involving life-threatening effects, mean age at the time of the bite, remaining life expectancy, and risk of disability. The price of treatment included all costs related to patient care including logistics and the risk of serious side effects and the cost of the antivenom. This demonstrated that treatment using antivenom was highly cost-effective: a benefit higher than \$2,330 per death averted and nearly \$100 per year of life adjusted for permanent disability. Subject to proper management of envenoming, systematic use of antivenom is likely to reduce mortality and permanent disability by 90%, not to mention the reduction in the duration and costs of hospitalization. Antivenom treatment might well spare each year more than 38 million US dollars annually, 15.7 for deaths and 22.5 for preventable disabilities, representing more than double the cost of antivenoms and their administration.

Training of health personnel is based on a simple and appropriate treatment algorithm. Moreover, besides the initial training during medical or nursing school, it is necessary to ensure regular updating of knowledge.

The antivenom is administered intravenously, allowing rapid neutralization and elimination of constituents of the venom [64, 65]. The dose is determined by the amount of venom injected by the snake, estimated by the clinical effects, and is identical for all victims including children. There is no pediatric or patient weight-based dosing.

In mild envenoming (i.e., without bleeding or neurological disorders), the administration of a minimal dose is usually sufficient. Depending on the type of antivenom and type of snake, this may be as little as a single vial. The presence of a hemorrhagic or neurologic syndrome requires the administration of more substantial doses (e.g., for some antivenoms this may equate to, respectively, two and four vials; see Fig. 8).

Fig. 8 Algorithm of snakebite treatment

However, dosage depends also on the neutralizing potency of the antivenom.

A first assessment of the efficacy of treatment should be carried out after 2–3 h and then at 6, 12, 24, and 48 h. A repeat dose of the antivenom can be given if bleeding or neurological disorders persist, worsen, or appear (Fig. 8).

Finally, the major remaining challenges concern the availability of appropriate antivenom and administration within a reasonable time, which ideally is less than 10 h after the bite, although late antivenom administration remains effective in some circumstances [66]. Antivenom when manufactured according to the recommendations of the World Health Organization [60] is generally expensive, one of the main reasons for the lack of antivenoms in peripheral health centers [15, 49, 50]. Conversely, many antivenoms are sold, often at low cost, but do not correspond to WHO recommendations and are dangerous or fake [67]. Table 5 lists the antivenoms currently used in Africa (it is important to note that the range of antivenoms available is changing, not static). Finally, the important delay in patients seeking medical care which is frequently observed is related to many factors such as treatment-seeking behavior [45, 47, 55], remoteness and poor supply

of health centers, poverty, and cost of treatment, all inducing a vicious circle leading to the abandonment of antivenoms [50].

Symptomatic treatment includes analgesics, anti-inflammatory drugs (avoiding salicylates if there is a hemorrhagic syndrome), and correction of hypovolemic shock and electrolytes, especially in hypotensive patients or those with significant complications (edema, necrosis, cardiopulmonary or renal failure).

Blood infusion or administration of blood substitutes (platelets, fibrinogen, fresh frozen plasma, etc.) should only be performed after the venom present in the victim has been neutralized by the antivenom. Otherwise, hemorrhagic syndrome may be reactivated [68].

Airway protection and artificial respiration should be initiated in cases of severe dyspnea or respiratory arrest. Kidney failure is treated by peritoneal dialysis or hemodialysis when it is feasible.

Compartment syndrome, provided that the diagnosis is confirmed by measuring intracompartmental pressures, should be treated by a fasciotomy. However, the high risks of complications (bleeding and secondary infections in particular) and significant sequelae (unsightly scars and

Table 5 Availability and characteristics of African antivenoms

^dNo longer manufactured

functional impairments) must be considered, and surgical treatment should be used only after careful consideration [69] and only once any coagulopathy is reversed.

Necrosis will be treated surgically after final stabilization of the lesion (the spread of necrosis halted for 2 consecutive days and CPK decreased below 5,000 U/L).

Corticosteroids do not appear to have significant therapeutic value, whether to treat neurological symptoms [70] and edema [71] or to prevent early adverse reactions following antivenom administration [72].

Routine administration of antibiotics has not been fully evaluated [73]. However, it should be reserved for cases with confirmed bacterial infection and adapted to the circumstances and context.

First Aid

1. Reassure victims.
2. Immobilize bitten limb with splint or sling. Firm crepe bandage may be used as long as it does not compromise circulation (tourniquet effect); beware of progressive limb edema causing tightening of bandages resulting in circulatory compromise.

3. Remove any rings or other jewelry from the bitten limb (to prevent them becoming constrictive if swelling develops).
4. Observe airway and ensure airway patency. Support respiration if impaired.
5. Hasten transfer to hospital and take dead snake along if feasible.
6. Avoid harmful and time-wasting procedures such as incisions, applications of native herbs, black stones or extracting devices, electroshock, and application of icepacks.
7. Avoid use of tourniquets, constricting bands, etc., as it has been shown to have minimal or no beneficial effects unless the snake was identified as a dangerously neurotoxic elapid and medical care can be reached in under 40 min from time of application.
8. Relieve pain with oral paracetamol.
9. Irrigate eyes with plenty of clean flowing water following cobra venom spits in eyes.

Hospital Care

1. All victims should be admitted to the hospital for at least 24 h (better if less than 10 h) except in clear nonvenomous bites where snake has been reliably identified by an expert.

2. Pain may be managed with either oral paracetamol or narcotics. Tramadol may be substituted for narcotics. **Aspirin and non-steroidal anti-inflammatory drugs (NSAIDs) may aggravate bleeding and should therefore be avoided. Beware of respiratory depressant medications, particularly in bites by neurotoxic species (elapids).**
3. Persistent vomiting may be treated with antiemetics such as intravenous chlorpromazine, metoclopramide, or ondansetron. Antivenom may sometimes also reduce GIT symptoms of envenoming.
4. Intramuscular injections should be avoided in bites where coagulopathy might occur because of the likelihood of significant local hematoma formation. Bites by any viper or boomslang or vine or twig snake may carry such a risk, but bites by African elapids are not currently noted as causing coagulopathy.
5. Clinical evaluation of victims:
 - (a) History – elicit site of bite, circumstances of bite, time of bite, type of snake, severity of bite, number of bites, local features, and systemic features, plus past medical history, any medications, and past exposure to snakebite or antivenom
 - (b) Examination:
 - (i) Elicit vital signs, blood pressure (BP), heart rate (and regularity), respiration, and urine output.
 - (ii) Note severity and nature of local injury (extent and girth of swollen limb compared to healthy limb) and local bleeding. These initial and subsequent daily measurements would be used to monitor progress and effectiveness of interventions. If possible mark the upper/outer extent of swelling, noting the date and time; this allows assessment of progression of swelling. Check for enlargement or tenderness of draining lymph nodes in groin or axilla.
 - (iii) Elicit presence of systemic bleeding [bleeding from oro-gingiva, nose, vomitus, urine, stools, skin], neurologic abnormalities [drooping eye lids (ptosis), other cranial nerve paresis, drooling, respiratory muscle weakness, impaired consciousness, meningism], cardiac arrhythmias, pulmonary edema, renal angle tenderness, and other abdominal tenderness (possibility of retro-abdominal bleeding in patients with severe coagulopathy, notably saw-scaled viper bites).
 - (c) Investigate:
 - (i) Do the 20 min whole blood clotting test (20WBCT). In this test 2 ml of venous blood is placed in a new, clean, dry, glass test tube and left undisturbed for 20 min at room temperature. The tube is then tipped to see if blood runs out or has clotted.
 - (ii) Packed cell volume and full blood counts, blood film morphology, urea, electrolytes and creatinine, liver function tests, PT-PTT, and fibrin degradation products. Group and crossmatch for whole blood transfusion. (Note: All of these tests will likely be unavailable in a rural African health center setting, but should be utilized in a developed nation setting, when dealing with an exotic snakebite.)
6. Intravenous fluids should be given to patients especially those with hypotension or shock who require an IV fluid load. Infusion of dopamine may be considered in refractory shock.
7. Antivenom should be administered if indicated, as “poisonous (venomous) snakebite is not necessarily the same thing as snakebite poisoning (envenoming),” and bites may also be by nonvenomous snakes (see Fig. 8).

Administration of antivenom is by slow intravenous infusion or injection in at least 10 mins (or at 1 ml per min). If available, dilution of antivenom in sterile IV fluid (normal saline or similar) may be useful, but is not mandatory.

Hypersensitivity reactions are not uncommon (5–30% depending on type of antivenom) and should be anticipated, ensuring adrenaline and resuscitation equipment are immediately available plus staff to use them, prior to commencing antivenom. Patients should be monitored closely for early adverse reactions like pruritus, urticarial rashes, hypotension, bronchospasm, and anaphylaxis.

Effectiveness of antivenom is judged by the clinical response, i.e., reduction in limb swelling through daily measurement of extent and girth, bleeding from bite site, 20WBCT, and changes in clinical or biological features.

Anticoagulants have no place in management.

8. Fresh whole blood may be required with low hematocrit and/or active bleeding, once sufficient antivenom has been administered.
9. Patients with neurotoxic envenoming should:
 - (a) Be given a Tensilon (edrophonium) test: atropine sulfate is given intravenously (50 µg per kilogram without exceeding 0.6 mg) followed by an injection of edrophonium chloride (0.25 mg per kilogram without exceeding 10 mg); if the test is positive, continue as per below; otherwise (if negative) observe and monitor.
 - (b) Be considered for anticholinesterase agents (neostigmine: three intravenous injections of 2.5 mg each at 30 min intervals) as it may improve neuromuscular transmission abnormality if the Tensilon test is positive. Note this is not an alternative to antivenom, but rather a short-term ancillary treatment. If there is no discernible response to neostigmine, it should be ceased.
 - (c) Be continuously assessed for airway or respiratory compromise, and if this develops, immediately receive at least airway protection and respiratory support, preferably intubation and mechanical ventilation in an ICU setting. Manual Ambu bagging may be needed

temporarily until intubation and ventilation can be implemented.

10. After discharge victims should be followed up 7–14 days post antivenom for features of late adverse reactions (e.g., serum sickness). Patients who have received antivenom should be given clear instructions, prior to discharge, about the symptoms of serum sickness and advised to seek medical care if these develop.
11. Manage and rehabilitate disabilities like amputations, blindness (from venom ophthalmia), limb contractures, etc.
12. Provide psychological support for all snakebite patients, especially those who have had major envenoming, to reduce the extent of post-snakebite depression and other psychological effects of such a stressful event.

Special Risk Groups

Children

Snakebites in children are less frequent than expected considering the youth of the African population [3]. However, they are especially serious, firstly because the volume of distribution is reduced, resulting in a higher concentration of venom in the vascular compartment and deep organs, and secondly children are often bitten on the hand, which causes severe damage and disability [53].

Pregnant Women

Snakebites in pregnant women are rare but severe because of the risk of placental bleeding, abortions, and death in utero [74, 75].

Elderly

They are subject to more frequent complications (renal failure, cardiac, respiratory, hemorrhagic or ischemic stroke, etc.).

Indications for ICU Admission

In Africa, ICUs are rare and often very distant from places where bites occur. In addition, patient evacuation to an ICU is complex because transportation means are deficient (no ambulance, no cars or helicopters), the roads are often in poor condition, and patients are unwilling to go far from home and may not be able to afford the cost of either the transport or the higher-level hospital care:

1. Three major circumstances must, however, lead to consideration of hospitalization in an ICU.
2. Severe edema considering diameter or extension, with the disappearance of distal pulses, can cause compartment syndrome, requiring fasciotomy. Additional tests should be performed in an ICU: intracompartmental pressures, necessary to assess the need for fasciotomy, ultrasound, etc.
3. Patient with systemic bleeding that does not stop in 1 hour after antivenom administration, especially if treatment has been renewed, should be evacuated to an ICU where additional blood coagulation tests could be done.
4. A patient showing neurological syndrome with dyspnea or respiratory paralysis that fails to improve after administration of four vials of antivenom must also be evacuated for ICU admission where resuscitation, intubation, and prolonged ventilation can occur.

Common Errors and Misconceptions

- Ineffective treatment may be due to the use of inappropriate antivenom.
- Ineffective treatment can also be due to an inadequate dose: dose depends on the amount of venom inoculated which is assessed by the symptomatology; the dose should be identical regardless of age or weight.
- Unnecessary repetition of antivenom: neither edema nor the 20WBCT are good

criteria for the repeating antivenom administration because of delayed normalization. The best criteria for the renewal of antivenom are the persistence or relapse of bleeding or neurological disorders.

- Blood infusion or administration of blood substitutes too early, i.e., before the antivenom has neutralized the venom, may induce the relapse of hemorrhagic syndrome due to consumption of the injected blood factors.
- Post-therapeutic follow-up should continue for 2 or 3 weeks: serum sickness appears in about 15% of treatments, in 7–15 days after the treatment [76].

Key Points

- Population at risk is young (15–45 years) and predominantly male.
- Over 95% of deaths occur in rural areas.
- Over 90% of victims consult a traditional healer at first instance, and 30–50% of them do not attend a modern health center.
- More than half of the victims arrive at the health center more than 10 h after the bite.
- Using a polyvalent antivenom may avoid having to identify the snake. Note: Available polyvalent antivenoms do not cover all major snake species (notably boomslangs are not covered and require a specific antivenom).
- The effectiveness of the new generation of polyvalent antivenoms reduces mortality by nearly 90%.
- The cost-benefit ratio of antivenom use is particularly excellent despite initial investments.
- Although there is evidence of antivenom efficacy and benefits, availability remains low particularly in remote health facilities.
- The training of health personnel is currently insufficient.

Overview

Asia, the largest landscape on Earth, provides habitat to the majority of Earth's human beings as well as to a colossal diversity of snakes. More than 150 venomous species, representing several snake families: the Viperidae (e.g., vipers, pit vipers, and Fea's viper), the Elapidae (e.g., kraits, cobras, king cobras, and Asian coral snakes), and the broad assemblage previously contained within Family Colubridae (e.g., non-front-fanged-colubrids (NFFC snakes), including "rear-fanged" snakes) are known to exist.

Asia has the highest incidence of snakebite in the world [1]. Due to sociocultural structures and views, snakes are regarded very differently in Asia than in other parts of world, and for many Asian people, snake encounters are a daily occurrence. In many areas, snake envenomation is regarded as an occupational hazard. Certain occupations, such as rice farming, rubber harvesting, forestry, and fishing, are known to be associated with an increased frequency of snakebite. They are also known to have a seasonal variation mostly related to monsoon and harvesting. Natural calamities like flooding also increase the chance of encounter by forcing snakes and humans into closer contact. In Bangladesh, during the flood of 2007, snakebite was the cause of the second highest mortality after drowning [2]. In many parts of India, Sri Lanka, and Southeast Asia, snakebite has increased along with more recent agricultural development projects. The need for arable land, in particular rice fields, has destroyed habitat and displaced snakes into populated areas. In many regions, people share their living place with cattle and stored grains. This practice has increased the chance of snake-human encounters by attracting rodents and the snakes that prey on them. Throughout much of Asia, the rural poor are the main victims of snake envenomation. In those resource limited settings, inadequate and inaccessible medical care and the high cost of treatment compound the damaging effects of snakebite. The cost of treatment and loss of daily wage may be as high as the average per capita income. When the primary wage earner of the household is disabled

as a result of snakebite, the ensuing economic hardship may impoverish entire families [3].

The emerging economies of Asia, in particular in India, Thailand, and Vietnam, have driven improvements in medical care and in many regions have increased the number of medical intensive care units (ICUs). The availability of ICUs allows for improved care of severely envenomed patients. A correlate scenario is found in Western countries, where patients bitten by imported species benefit from ICU-level monitoring and treatment.

This chapter mainly focuses on the assessment and management of Asian snake envenomation with a focus on both treatment in resource-constrained settings typical of small hospitals in rural Asia and treatment in modern ICUs. Detailed herpetological, morphological, or taxonomic discussion of snakes and ultrastructural in-depth discussion of pathophysiology are beyond the scope of this chapter. The physician caring for patients envenomed by Asian species can benefit from an understanding of the snakes themselves. For this reason, a brief natural history of important Asian species and unique features of their venom are presented. An overview of snake venoms is presented in another chapter.

There is no reliable bedside diagnostic test kit available in most parts of Asia to determine the identity of the offending snake. Only a limited number of patients present with the caught culprit snake and description by the victim are not always available or reliable. Thus physicians must rely on the constellation of symptoms and signs resulting from envenomation. These "syndromes" play a key role in the effective treatment of snakebite patients. Examples of this information at work include the rapid diagnosis of nonenvenoming or "dry" bites and rapid bedside determination that the bite was caused by a viper, a rear-fanged "colubrid," or an elapid (e.g., coral snake, krait, or cobra). Envenoming by Asian coral snakes (*Calliophis*) and kraits (*Bungarus*) produces minimal local reactions but results in severe systemic neurotoxicity; missing these diagnoses can have tragic consequences. In contrast, cryptic envenoming by Asian cobras is unlikely to occur

because the venom of most species causes significant local reactions. In the case of Asian vipers, envenoming is *reliably confirmed* by the presence of pain, swelling, ecchymosis, or bleeding from fang marks. This finding is *not always true* for viper bites in other parts of the world. Conversely, bites by the rear-fanged yamakagashi (*Rhabdophis*) may cause minimal local symptoms but result in systemic coagulopathy. An understanding of the spectrum of these envenoming syndromes allows the physician to make decisions regarding optimal therapy for each case and to avoid mishaps in antivenom selection. Familiarity with the characteristics, range, and habits of snakes, a detailed clinical history covering the circumstances of the bite, and an appreciation for the clinical effects of envenoming are beneficial in suggesting the responsible species when the snake itself is not available [4].

Kinematics of Asian Snakebite

In humans, the evolution of snake envenomation and outcome depends on the amount and composition of venoms injected. Venom antigenemia has been found to correlate with clinical severity in several species of snakes including Burmese Russell's viper [5]. Bites by venomous snakes, including the most dangerous Asian species, include cases of nonenvenoming. The observations that snakes invariably strike humans in defense and that 15–45% of these bites are nonenvenoming have suggested to some that the snakes regulate the amount of venom injected based on circumstance. In the field, when snakes are trod on and respond reflexively with a strike, the event seems to take the snake and the human by surprise. It is likely that the serpent's sudden and desperately delivered strike often results in incomplete fang penetration. Factors that interfere with envenoming include inefficient strike trajectories, such as when the snake delivers a backward strike to the foot that stepped on it; the large size, shape, and unfamiliarity of humans as targets; and the interference caused by clothing and footwear. The idea that a snake's venom has been exhausted after a recent strike, and therefore the snake will

be less venomous after eating, or after striking another victim, has been refuted [5]. The opposite scenario is also a cause for concern, such as when the patient is bitten by a captive and habituated venomous species. A high percentage of these cases occur when captive snakes smell food animals in advance and anticipate imminent feeding. Hungry, enthusiastic specimens may confuse the caretaker's hand for a food animal and respond with a venom-laden strike. Snakebites that occur during the feeding of captive specimens often produce effects more severe than those seen after defensive bites by wild specimens. Details surrounding snakebite involving captive specimens require close investigation because these cases may prove to be particularly severe [6]. The severity of envenoming tends to increase with the size of the offending snake, although the largest of specimens do not always inflict the most venomous bite and juveniles of some species can deliver lethal bites.

Representative and significant Asian terrestrial species are listed in Table 1 and many genera, with approximate distribution maps and some representative species are shown in Figs. 1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12, 13, 14, 15, 16, 17, 18, 19, 20, 21, 22, 23, 24, 25, 26, 27, 28, 29, 30, 31, 32, 33, 34, 35, and 36. The determination of the range is derived from reports in the herpetology literature or case series of snake envenoming. The species presented are representative of the genus, are responsible for significant mortality, or possess venom with unique clinical properties.

Regional Distribution and Pathophysiology

Asia is the only region on earth where all three Viperidae subfamilies are found: the Viperinae, or Old World vipers; the more advanced Crotalinae, or pit vipers; and the Azemiopinae, containing the attractive monotypic species, Fea's viper (*Azemiops feae*), found along the China-Laos-Vietnam border.

Physicians with experience treating snakebite in Asia generally agree that although elapids (cobras and kraits) account for the most deaths, vipers cause the most bites (Figs. 37, 38, 39, and 40).

Table 1 Terrestrial Asian venomous snake families and representative species

Family	Genus	Species	Common Name	Range
Viperidae (Azemiopinae)	<i>Azemiops</i>	<i>A. feae</i>	Fea's viper	Vietnam, Laos
Viperidae (Viperinae)	<i>Cerastes</i>	<i>C. gasperettii</i>	Horned sand viper	
	<i>Daboia</i>	<i>D. russelii</i> complex	Russell's viper	Asia
	<i>Echis</i>	<i>E. multisquamatus</i>	Tibetan saw-scaled viper	Western Asia
	<i>Vipera</i>	<i>V. xanthina</i>	Steppe/ottoman viper	Western Asia
Viperidae (Crotalidae – pit vipers)	<i>Gloydius</i>	<i>G. brevicaudus</i>	Chinese mamushi	Southern China
	<i>Calloselasma</i>	<i>C. rhodostoma</i>	Malayan pit viper	Southern Myanmar–Malaysia–Java
	<i>Deinagkistrodon</i>	<i>D. acutus</i>	Sharp-nosed viper	North Vietnam–central China
	<i>Hypnale</i>	<i>H. nepa</i>	Sri Lanka hump-nosed viper	Sri Lanka

Fig. 1 Russell's viper, *Daboia russelii* (specimen from West Bengal). This widely distributed snake, with two closely related species (*D. russelii* and *D. siamensis*) is among the most medically important venomous snakes of the Asian region, accounting for large numbers of cases and fatalities. The venom shows great regional variation, such that the clinical picture varies depending on which geographic population of Russell's viper is considered, with effects that can include one or more of local pain, local necrosis, local ecchymosis, shock, coagulopathy, AKI, systemic bleeding, anterior pituitary infarction/Sheehan's syndrome, rhabdomyolysis, neurotoxic paralysis (Photo copyright © Dr. Julian White)

The venom of Asian vipers is rich in enzymes, which induce local pain, swelling, tissue damage (Figs. 41 and 42), coagulopathy (Figs. 38, 39, 40, and 43), and, for some species, damage to the

Fig. 2 Russell's viper, *Daboia russelii* showing erect fangs (Photo copyright © Dr. Julian White)

kidneys, the adrenals, or the pituitary gland. Postenvenoming sequelae after viper bites account for significant disability among certain occupational groups, such as rubber plantation workers and rice farmers.

An understanding of the habits, range, and preferred niche of certain viper species provides meaningful epidemiologic clues to the treating physician. Bite injuries to the hands of fruit and coffee plantation workers in Central Malaysia or

Fig. 3 Russell's viper, *Daboia siamensis* (Thailand)
(Photo copyright © Dr. Julian White)

home gardeners living in Bangkok or wood cutters in Bangladesh commonly are caused by the arboreal green tree vipers (*Trimeresurus*; Figs. 11, 12, 13, and 14) [7], rubber-tappers in Southeast Asia often fall victim to Malayan pit viper (*Calloselasma rhodostoma*; Figs. 9 and 10). In contrast, nocturnal bites to the feet caused by ground-dwelling vipers in Pakistan, India's arid plains, and the Shavakacheri region in Sri Lanka usually are caused by saw-scale vipers (*Echis*; Figs. 5, 6, 7, and 8). Bites in less arid areas, especially in rice paddies, from Sri Lanka, through India, Myanmar (Burma), into SE Asia and as far east as Taiwan are commonly caused by varieties of Russell's viper (*Daboia* spp.; Figs. 1, 2, 3, and 4).

Natural History of Important Species and Unique Features of Their Venom

Viperidae

The venoms of Asia's vipers, similar to the vipers themselves, are not without their peculiarities. The venom of most species contains a mixture of peptides with direct toxic or indirect enzymatic activity. From a clinical standpoint, the most important of the proteolytic enzymes are the phospholipases A₂ myoneurotoxins [8], which destroy tissue and serve as presynaptic neurotoxins, and

Fig. 7 Saw-scaled viper, *Echis sochureki* (Photo copyright © Dr. Julian White)

shock-inducing hemorrhagins [9], which destroy blood vessel walls, leading to extravasation and third spacing of fluid. Additional enzymes possess procoagulant, anticoagulant, and fibrinolytic activity. More recently, unique disintegrins have been identified in the venom of several species; these disintegrins inhibit platelet aggregation by preventing von Willebrand's factor and fibrinogen from binding to platelet (glycoprotein IIb/IIIa) integrin receptors [10].

In the first 48 h after viper bite, death may result from the effects of defibrination-related hemorrhage, shock secondary to vascular leak, or, in several species, respiratory paralysis. Death after 72 h is more likely to result from internal (especially intracranial) hemorrhage, renal failure, adrenal insufficiency, or secondary infection arising from necrotic tissues. Several clinical aspects of Asian viper venom require additional discussion.

Local Effects

Local envenoming is usually more severe than that caused by other non-Viperid snake species. Local swelling and erythema result from the combined effects of vasoactive compounds and enzymatic toxins. Swelling may develop immediately or may take several hours. Spread may be slow or rapid involving the whole limb and adjacent trunk. There may be associated pain, tenderness, and local/regional lymphadenopathy. Blisters

Fig. 8 Approximate distribution for saw-scaled vipers, genus *Echis*, within Asia (note other *Echis* spp. found in the Middle East and parts of Africa) (Map copyright © Dr. Julian White)

containing clear or blood stained fluid may appear near the bite site within a few hours. Necrosis of skin, subcutaneous tissue, and muscles occur in about 10% of hospitalized cases for some vipers, especially in pit vipers (e.g., *Calloselasma*, *Deinagkistrodon*, some *Trimeresurus*) and saw-scaled vipers (*Echis*). Bites on digits or in areas draining into tight fascial compartment (anterior tibial compartment) are particularly likely to develop raised intracompartmental pressure resulting in ischemia. Together with direct effects of venom this is more likely to result in necrosis [11]. Raised intracompartmental pressure should be suspected when there is severe pain associated with tense swelling, segmental anesthesia, and pain on stretching the intracompartmental muscles (e.g., dorsiflexion of the

foot). In viper bite, local toxicity is usually universal and absence of local swelling 2 h after bite usually means absence of venom, but systemic envenoming by the Burmese Russell's viper (*Daboia siamensis*) may occur in the absence of local signs. Local tissue necrosis results from the direct action of myotoxins (phospholipases A_2) and cytotoxins. The factors responsible for increased vascular permeability leading to local swelling and bruising, include endopeptidases, metalloproteinase hemorrhagins, membrane-damaging polypeptide toxins, phospholipases, and endogenous autacoids such as histamine, 5-hydroxytryptamine, and kinins. The presence of coagulopathy is first noted at the bite site, where incoagulable blood drains from teeth and fang marks. Local necrosis may be significant

Fig. 9 Malayan pit viper, *Calloselasma rhodostoma*. This snake can cause marked local pain, swelling, ecchymosis, blistering, shock, severe coagulopathy, and systemic bleeding (Photo copyright © Dr. Julian White)

after envenoming by the Malayan pit viper (*Calloselasma*), Russell's vipers (*Daboia*; Figs. 41 and 42), green tree vipers (*Trimeresurus*), and saw-scaled vipers (*Echis*), all of which are discussed subsequently. Minor necrosis may follow envenoming by hump-nosed vipers (*Hypnale*), hundred pace viper (*Deinagkistrodon*; Figs. 23 and 24), habus (*Ovophis*; Figs. 17 and 18), and Mamushis (*Gloydius*; Figs. 19 and 20).

Systemic Effects

Coagulopathy

The most common systemic symptom after envenoming by Asian *Daboia*, *Trimeresurus*, *Calloselasma*, and *Echis* spp. is coagulopathy (Figs. 38, 39, 40, 43, 44, and 45). Viper venom

Fig. 10 Approximate distribution for the Malayan pit viper, *Calloselasma rhodostoma* (Map copyright © Dr. Julian White)

Fig. 11 Common green pit viper, *Trimeresurus albolabris*. This snake, common in urban/semiurban environments within its range, can cause moderate to severe envenoming, with local pain, swelling, ecchymosis, and systemic coagulopathy. In more severe cases there can be shock, with rare cases of local necrosis and AKI reported (Photo copyright © Dr. Julian White)

Fig. 13 Brown-spotted green pit viper, *Trimeresurus venustus*. This species, in the past included within *T. kanburiensis*, may cause at least moderate envenoming with local pain, swelling, ecchymosis, possibly shock, systemic coagulopathy, and bleeding (Photo copyright © Dr. Julian White)

Fig. 12 Approximate distribution for snakes of genus *Trimeresurus* (Map copyright © Dr. Julian White)

Fig. 14 Indian green pit viper, *Trimeresurus gramineus*. Though common, little information on the clinical effects of bites by this snake are documented, but like many other green pit vipers across Asia, it may possibly cause both local pain and swelling and ecchymosis and shock with systemic coagulopathy, as the venom contains a variety of coagulopathic and hemorrhagic toxins (Photo copyright © Dr. Julian White)

Fig. 15 Japanese habu, *Protobothrops flavoviridis*. This species and other habus, such as the Chinese habu, *P. mucrosquamatus*, can cause moderate to severe envenoming, with local pain, swelling, ecchymosis, blistering, necrosis, shock, and systemic coagulopathy and bleeding, AKI are possible, at least for some species (Photo copyright © Dr. Julian White)

contains procoagulants and procoagulant activating factors that can activate intravascular coagulation resulting in consumption coagulopathy. Some of them have a direct thrombin-like action on fibrinogen, while others activate the

endogenous fibrinolytic system. Anticoagulant activity is due to phospholipases. Thrombocytopenia is a frequent finding, most likely caused by platelet agglutination. Spontaneous systemic bleeding results from damage to vascular endothelium due to the action of distinct venom components, hemorrhagins. The combination of incoagulable blood, thrombocytopenia, and vessel wall damage may produce massive local and systemic bleeding which may be fatal. In the hospital setting, a leading cause of death is spontaneous hemorrhage or iatrogenic hemorrhage resulting from attempts at vascular access or ill-advised attempts at fasciotomy. Bleeding into anatomic compartments, such as the muscles of the thigh and the retroperitoneum, should be suspected and actively searched; otherwise they may be missed until hypotension/shock results.

Neurotoxicity

The venom of several Asian vipers – the *Daboia*/Russell's viper group and several species of mamushis (*Gloydius*) – contains neurotoxins. In southern India and Sri Lanka, envenoming by local *Daboia* subspecies (*Daboia russelii russelii*; previously, *Daboia russelii pulchella* in Sri Lanka) can cause neurotoxic symptoms, in addition to intravascular hemolysis and myolysis seen throughout the species' range [12]. In severe cases, *Daboia*-induced paralysis may progress to the respiratory muscles [13]. The neurotoxin is a phospholipase A₂. In Japan, China, and South Korea, envenoming by several subspecies of mamushi (*Gloydius blomhoffii brevicaudus* group) also can result in neurotoxic symptoms ranging from mild ptosis to complete respiratory paralysis [14–17]. Envenoming from two other *Gloydius* spp., the Ussuri mamushi (*Gloydius ussuriensis*) [18, 19] and the central Asian pit viper (*Gloydius intermedius*) [20], also is reported to cause neurotoxic symptoms, although these seem to be less severe.

The venom of many Asian viper species differs among regions. Asian vipers known to have geographically heterogeneous venom are *Daboia*, *Calloselasma*, *Echis* (particularly between Asia and Africa), and *Trimeresurus* spp. The variability

Fig. 16 Approximate distribution for snakes of genus *Protobothrops* (Map copyright © Dr. Julian White)

Fig. 17 Mountain viper, *Ovophis monticola*. These snakes can cause at least moderate envenoming with local pain, swelling, ecchymosis, and systemic coagulopathy and bleeding (Photo copyright © Dr. Julian White)

in venom is reflected by heterogenous results with antivenom treatment. Economic constraints in antivenom manufacture often result in the use of venom from snakes whose collection was convenient, usually from the region where the antivenom was produced. Antivenoms are rarely prepared using pooled venom obtained from specimens from different regions. Many antivenoms may not effectively neutralize the venom of the same species from another region. This observation has implications for health centers that are purchasing antivenom from foreign manufacturers and for pharmacists who need to protect zoo and research personnel from bites by imported species.

Fig. 20 Approximate distribution for snakes of genus *Gloydius* (Map copyright © Dr. Julian White)

the range of clinical effects seen in patients envenomed by species from different regions.

In addition to phospholipase A₂ myoneurotoxins, Russell's viper venom contains hemorrhagins, platelet-aggregating factors, and venom enzymes that activate factor V, IX, and X and induce fibrinolysis [22]. In certain regions, Russell's viper venom also possesses plasminogen and antiplasmin activity. Together, these factors induce chaotic activation of extrinsic and intrinsic coagulation pathways with simultaneous formation and destruction of blood clots. *De novo* thrombus formation, presenting as cortical disturbances, syncope, and sudden cardiac death, is rare but may occur soon after intravenous envenoming. The result of these clotting

abnormalities is eventual defibrination with marked elevation of fibrin degradation products [22]. Intravascular hemolysis is variable after Russell's viper envenoming.

Differences in venom composition have resulted in variations in the clinical manifestations of envenoming throughout the range of distribution [23–28]. The clinical presentation of envenomed patients may vary dramatically among regions. Throughout the range, the procoagulant effects of Russell's viper venom may cause consumption of fibrinogen and incoagulable blood. In eastern Pakistan and central India, envenoming by *D. r. russelii* also causes intravascular hemolysis and excessive damage to local skeletal muscle. In Sri Lanka and southern

Fig. 21 Temple pit viper, *Tropidolaemus wagleri*. Most bites by this common snake cause only mild-to-moderate local envenoming with pain, swelling, possibly ecchymosis, rarely necrosis, but it is unclear if they can also cause shock and coagulopathy (Photo copyright © Dr. Julian White)

India, however, envenoming by local *D. r. russelii* (previously *D. r. pulchella* in Sri Lanka) may result in neuromyotoxic symptoms (attributable to PLA₂) that can progress to respiratory paralysis and rhabdomyolysis. In Sri Lanka, reported features are ptosis (77%), external ophthalmoplegia (82%), inability to open the mouth (23%), to swallow and protrude the tongue, generalized muscle tenderness (32%), and myoglobinuria (27%). Most patients showed evidence of intravascular hemolysis. Panhypopituitarism, presenting between 1 month and 1 year after the bite, was reported from Kerala, south India (7 out of 1000 cases). The clinical presentation of envenoming also varies in the eastern species, *D. siamensis*. In Myanmar, envenoming by *D. siamensis* is more likely to be severe, characterized by a systemic capillary leak syndrome,

Fig. 22 Approximate distribution for snakes of genus *Tropidolaemus* (Map copyright © Dr. Julian White)

Fig. 23 Hundred pace snake, *Deinagkistrodon acutus*. This snake causes moderate to severe envenoming with local pain, severe swelling, ecchymosis, blistering, necrosis, shock, systemic coagulopathy, and bleeding (Photo copyright © Dr. Julian White)

conjunctival hyperemia (chemosis), pulmonary edema, and infarction of the anterior pituitary gland [29, 30]. Systemic capillary leak syndrome, first described for Russell's viper bite in Burma, characterized by orbital and conjunctival edema with conjunctival hemorrhages (Fig. 46 and 47), develops in severe cases and is evidence of generalized increase in capillary permeability. Other manifestations of this permeability syndrome are facial edema, pleural effusions, ascites, pulmonary edema, and transient proteinuria with hypoalbuminemia [31]. In Thailand, though the snake is the same species as in Myanmar, clinical features are generally less severe; the most severe complications resulting from incoagulable blood and renal failure. In Indonesia, an isolated population of *D. siamensis*, separated by more than 2000 km from the nearest consanguineous species, is implicated in bites with an excessively high case-fatality rate of 38.5% and a mean interval between bite and death of only 14.5 h, far faster than that observed in other parts of the species' range [32] (Table 2).

Despite the variability in presentation, all Russell's viper venoms produce some pain and swelling within minutes of envenoming. Pain and swelling may be less significant in Madras, India, and Sri Lanka than observed elsewhere.

Clinical events reflecting the activity of the venom include pain, swelling, ecchymosis, and bulla formation [35, 36]. Within 1 h of envenoming, evidence of regional coagulopathy is manifest by persistent bleeding from fang and maxillary teeth wounds. The combined loss of blood from fang marks, intravenous (IV) access sites, and the gastrointestinal and urinary tract [37] is often considerable, contributing to hypovolemia and hemorrhagic shock. Local necrosis is common in many parts of the Russell's viper range (Figs. 41 and 42), although it is less severe than necrosis after envenoming by *Calloselasma rhodostoma* (Malayan pit viper) and many species of cobra (*Naja naja*; Fig. 48), which share much of the range.

In southern India, Sri Lanka, Myanmar, and Thailand, Russell's viper envenoming is a common cause of renal failure [37–41]. In Kerala, India, Russell's viper envenoming is the leading cause of acute renal failure in adults and children [38]. Clinical evidence that Russell's viper venom contains a unique nephrotoxin is supported by the high incidence of renal failure in patients with negligible coagulopathy, rhabdomyolysis, or history of hypotensive episodes and with recent identification of a nephrotoxic effect [42]. Renal biopsy data has shown a variety of histopathological changes including proliferative glomerulonephritis, toxic mesangiolysis with platelet agglutination, fibrin deposition, ischemic changes, acute tubular necrosis, distal tubular damage ("lower nephron nephrosis") suggesting direct venom nephrotoxicity, and bilateral renal cortical necrosis with subsequent calcification [43].

In Taiwan, bites by local *D. siamensis* (formerly *D. r. formosensis*) are a leading cause of acute renal failure and are implicated in neurotoxicity [40]. The neurotoxin of this species was found to constitute 40% of the venom and to consist of two distinct phospholipases, which combine to produce a postsynaptic neurotoxin [44, 45].

Little is known about the clinical effects of Russell's viper envenoming in mainland China. One epidemiologic study indicated that Chinese Russell's vipers account for fewer bites than other

Fig. 24 Approximate distribution for the hundred pace snake, *Deinagkistrodon acutus* (Map copyright © Dr. Julian White)

species (e.g., *Trimeresurus*, *Gloydius*). Although specimens from southern China are morphologically similar to specimens in neighboring north-western Laos, northern Thailand, and Myanmar (variant *D. siamensis*), few comments can be made with regard to characteristics of the venom. One case series studying bites by *Trimeresurus albolabris* mentioned a single case of envenoming by an imported Chinese Russell's viper, resulting in defibrination, intracranial hemorrhage (Fig. 45), acute renal failure, and death. Along the Thailand-Laos border, 18 cases of confirmed envenoming by *D. siamensis* treated by the author developed prolonged clotting times, hemolysis, microalbuminuria, hemoglobinuria, and

hemorrhagic bulla formation. Mild necrosis was present in three bites to the hand or fingers. None of these patients developed acute renal failure. One patient developed severe pulmonary hemorrhage requiring blood transfusion, prolonged respiratory support, and antivenom therapy.

Neurotoxicity after Russell's viper envenoming is seen most frequently in Sri Lanka, southern India (*D. russelii*), and Taiwan (*D. siamensis*). In one Sri Lankan series, envenoming ("*D. r. pulchella*") resulted in diplopia and ptosis between 30 min and 7 h after the bite [8]. Compared with envenoming by *Naja* and *Bungarus*, neurotoxicity resulting from Russell's viper bites tends to be less severe; however,

Fig. 25 Malayan krait, *Bungarus candidus*. Kraits cause minimal local effects, no necrosis, but progressive onset of moderate to severe flaccid neurotoxic paralysis, but not coagulopathy. In some species there may be systemic rhabdomyolysis and hyponatremia, and severe abdominal pain is a common feature (Photo copyright © Dr. Julian White)

Fig. 26 Indian krait, *Bungarus caeruleus* (Photo copyright © Dr. Julian White)

progression to respiratory paralysis is known. In western India and Bangladesh, envenoming by local Russell's viper species induces coagulopathy, hypotension, renal failure, and anemia. In Myanmar, Russell's viper bites may cause incoagulable blood, hemolysis, acute renal failure (the commonest cause of acute renal failure in Myanmar), and endocrinopathies secondary to infarction of the anterior pituitary gland [30, 36, 46], but no evidence of neurotoxicity. Pituitary insufficiency may manifest months after envenoming when patients return with complaints

Fig. 27 Banded krait, *Bungarus fasciatus* (Photo copyright © Dr. Julian White)

of low libido, amenorrhea, loss of pubic hair, and diabetes insipidus [29, 47]. Postmortem examination of Russell's viper victims, for which there is no shortage of opportunities, shows hyperemia and congestion of vascular beds in the anterior pituitary gland, adrenal gland, gastrointestinal tract, and alveolar beds and within the coronary vessels. The well-studied venom phospholipase A₂, VRV-PL-VIIIa, has been implicated in alveolar hemorrhage and myotoxicity, neurotoxicity, and regional edema reported previously [48]. The variability between Russell's viper venoms from different regions has limited the usefulness of antivenoms produced in other countries [13, 49]. At present, there is considerable interest in the development of polyvalent/panregional Russell's viper antivenoms that would be effective throughout the species range.

Saw-Scaled Vipers (*Echis*)

The medically important genus *Echis* (saw-scaled viper; Figs. 5, 6, 7, and 8) is widely distributed, in the northern third of Africa from Senegal in the west, south to the Tana River in Kenya, through the Middle East and western Asia, as far north as the Aral Sea, and throughout the Indian subcontinent, including Sri Lanka and as far as the border of West Bengal. Each of the 12 *Echis* spp. is characterized as small, ground-dwelling vipers with disproportionally large eyes, a blunt snout, heavily keeled scales, and a pugnacious disposition. The saw-scaled viper's name arises from the

Fig. 28 Approximate distribution for snakes of genus *Bungarus* (Map copyright © Dr. Julian White)

noise created when the snake becomes irritated and rubs its keeled scales together to warn other animals. In captivity, *Echis* remain highly strung and prone to bite. In Asia, *Echis* bites are caused by three species: the far-ranging, prototypic *Echis carinatus*, which is found in peninsular India as far east as Maharashtra and Tamil Nadu; the largest and most dangerous species, *Echis sochureki* (Sochurek's saw-scaled viper), found in northern India to Pakistan; and *Echis multisquamatus* (central Asian saw-scaled viper), found in eastern Pakistan and northern India. In some areas of India and Pakistan (e.g., in Sind and Jammu), it is the major cause of snakebite morbidity and mortality [50, 51]. In southern India and Sri

Lanka, *Echis* (probably *E. c. sinhaleyus*) is infrequently implicated in envenoming.

The venom of *E. carinatus* activates factor X and prothrombin (both Group A and B prothrombin activators) and inhibits thromboxane-induced platelet activation. *Echis* venom also contains hemorrhagins, which contribute to vascular leak, third spacing of fluids, hypovolemia, and shock. As with the Russell's viper, local effects of *Echis* bites include pain, swelling, blistering, and discoloration, which often transition to ecchymosis and become necrotic. Lymphangitis and tender draining lymph nodes are common. The most important clinical feature of *Echis* envenoming is severe hemorrhage resulting from coagulopathy.

Fig. 29 (a) Indian spectacled cobra, *Naja naja*. A very common snake causing moderate to severe envenoming with local pain, swelling, sometimes ecchymosis, blistering, necrosis, and flaccid neurotoxic paralysis, but not

coagulopathy (Photo copyright © Dr. Julian White). (b) Indian spectacled cobra, *Naja naja* showing classic markings on the back of the hood (Photo copyright © Dr. Julian White)

Fig. 30 (a) Monocellate cobra, *Naja kaouthia*. These cobras cause similar effects to *Naja naja*, though possibly the local effects may be less severe and the neurotoxicity more prominent (Photo copyright © Dr. Julian White).

(b) Monocellate cobra, *Naja kaouthia* showing classic single eye marking on the back of the hood (Photo copyright © Dr. Julian White)

When the identity of the snake cannot be confirmed, the patient's description of the viper's unique defense behavior, time of day (night) of the bite, familiarity with the viper's range, environmental preference, and clinical presentation of pain, blistering, and coagulopathy provide sufficient evidence to support treatment with *Echis*-

specific antivenom [4]. As with Russell's viper, *Echis* venom is known to vary throughout the species' range. Cases of treatment failure using *Echis*-specific antivenom imported to treat bites in northern Nigeria [51] and Pakistan [52] serve as a warning for the clinician treating *Echis* bites with antivenom produced in other regions.

Fig. 31 Siamese spitting cobra, *Naja siamensis*. Spitting cobras, in addition to causing corneal pain and damage from spat venom, on biting cause local pain, swelling, and necrosis, but paralytic effects may be less prominent (Photo copyright © Dr. Julian White)

Malayan Pit Viper (*Calloselasma Rhodostoma*)

Adult vipers are thick-bodied, ground-dwelling, dark-colored snakes, usually covered with dark, triangular markings along the dorsum (Fig. 9). In many countries of Southeast Asia, the Malayan pit viper *Calloselasma* is either the most common cause of snakebite [53] or the most common cause of snakebite deaths [54]. It is likely that rural environs and failure to access medical care heavily influence the number of fatalities. *C. rhodostoma* is found throughout Thailand, Cambodia, Laos, West Malaysia, Sumatra, and Java (Fig. 10). A smaller subspecies is found in southwestern Vietnam and adjacent Cambodia. Throughout the species range, rubber and tea plantation workers, rather than rice farmers, are most commonly bitten; a major occupational hazard. This predilection reflects the species' preference for drier, alkaline soils; partial canopy; and preference for rodents, which concentrate around farms. A crepuscular hunter, the viper is most active when workers are traveling to and from the fields. Most cases occur when the snake is stepped on and the foot and lower leg are bitten.

Calloselasma venom contains ancrod, a potent serine protease that cleaves fibrinopeptide A from fibrinogen, which is used clinically as an

anticoagulant (Arvin) [55]. The protease works in concert with other venom antigens to defibrinate the patient's coagulation system. The process involves thrombin formation, often with sequestration of platelets; thrombocytopenia is a common laboratory finding after bites by this species. In most cases, the thrombocytopenia, but not the coagulopathy, resolves within hours of treatment with antivenom. A second feature of *Calloselasma* venom is the presence of proteases that specifically hydrolyze vitamin K-dependent clotting factors VII, IX, and X and protein C [56]. Early after envenoming by *C. rhodostoma*, a transient increase in the prothrombin time-to-partial thromboplastin time ratio is observed. The observation is of limited utility after the first few hours because generalized activation of extrinsic and intrinsic factors results in uniform elevation of prothrombin time and partial thromboplastin time.

There is minimal or no envenoming in about half of the patients, with local swelling starting within minutes and reaching its maximum after 24–72 h found in the rest. Patients bitten by *C. rhodostoma* may experience significant tissue destruction, which invariably extends beyond the border of bullae that form on the bitten extremity. The bullae contain bloody, rather than serous, fluid and closely resemble hemorrhagic bullae seen in New World rattlesnake (*Crotalus*) bites. The extent of blistering, bullae, and local tissue destruction is distinctive to *C. rhodostoma* envenoming, and in areas without Russell's viper and when cobra bites are unlikely, blistering, bullae, and local tissue destruction serve as an indication for preemptive treatment with *Calloselasma*-specific antivenom. Necrosis and gangrene complicating secondary infection by the bacteria from the oral cavity of the snake is common [57]. In one series, the leading cause of death after *Calloselasma* envenoming was cerebral hemorrhage followed by hemorrhagic shock [54].

Green Tree Vipers (*Trimeresurus* Species and Related Genera)

The genus *Trimeresurus* (Figs. 11, 12, 13, and 14) and related genera (*Protobothrops*, *Ovophis*;

Fig. 32 Approximate distribution for snakes of genus *Naja* (note other *Naja* spp.) found in the Middle East and parts of Africa (Map copyright # Dr. Julian White)

Fig. 33 King cobra, *Ophiophagus hannah*. The largest known venomous snake species, king cobras can cause moderate to severe envenoming with local pain, swelling, occasionally blistering and necrosis, shock, and rapid onset flaccid neurotoxic paralysis (Photo copyright © Dr. Julian White)

Figs. 15, 16, 17, and 18) covers an extensive range from Pakistan to Japan and south to the Philippines and the Indonesian islands. More than 36 species are recognized, including several ground-dwelling, brown-colored species (e.g., *Protobothrops mucrosquamatus* and *Protobothrops flavoviridis*); however, most of the species are arboreal, and most arboreal species are green. Genus *Trimeresurus* has been the subject of recent taxonomic contention, with the genus split into seven genera (*Trimeresurus*, *Cryptelytrops*, *Himalayophis*, *Parias*, *Peltopelor*, *Popeia*, *Viridovipera*), but most recently recombined into the single genus *Trimeresurus* for most species, except a few reassigned to

Fig. 34 Approximate distribution for the king cobra, *Ophiophagus hannah* (Map copyright © Dr. Julian White)

Fig. 35 Red-necked keelback, *Rhabdophis subminiatus*. This NFFC snake can cause severe systemic coagulopathy and bleeding, which may persist for several weeks and the related *R. tigrinus* has caused AKI; both can cause fatal envenoming. Local effects are usually minor (Photo copyright © Dr. Julian White)

Protobothrops. The term *green pit viper* is used with reservation because the designation has led to confusion in herpetology and medical literature and mishaps in the preparation of antivenoms. Similarities in coloration and intergrade species have confused the taxonomy, prompting efforts to define species using molecular approaches, rather than descriptions of range, eye color, and scale counts.

In Thailand, China, Japan, and several Asian islands, green tree vipers are the leading cause of venomous snakebite [53, 58]. Many *Trimeresurus* spp. are tolerant of human activity, and many bites occur in household gardens and urban parks. In parts of eastern Cambodia, the related Wagler's viper (*Tropidolaemus*) is found in Buddhist temples, where snake and monks coexist

Fig. 36 Approximate distribution for snakes of genus *Rhabdophis* (Map copyright © Dr. Julian White)

Fig. 37 Severe envenoming. The patient was a 13-year-old boy with respiratory paralysis 9 h after being bitten by an unknown krait (*Bungarus*). He received antivenom after symptoms appeared without effect, but he made a full recovery after 6 days of ventilation support. Note bulbar palsy

without apparent problems. Most *Trimeresurus* vipers are arboreal, which explains the high incidence of bites to the hands and the high occupational risk to fruit pickers, forestry workers, and gardeners. Many bites by the ground-dwelling pit vipers, *Protobothrops* spp. and *Trimeresurus* spp., such as the Chinese habu (*P. mucrosquamatus*) [59] and the Japanese/Okinawan habu (*P. flavoviridis*), occur in homes. In all regions, household envenoming is of great concern because it is more likely to involve children.

Similar to all vipers, the fangs of *Trimeresurus*, *Protobothrops*, and *Tropidolaemus* spp. are continuously replaced, although in these species, new fangs may move into position before older fangs are shed. Many *Trimeresurus* bites result in three or more fang marks at the bite site.

Fig. 38 A 23-year-old woman with severe envenoming by *Daboia russelii*. The splint and gauze bandage help to stabilize the bitten extremity. Coagulopathy is checked using the whole-blood clotting test. The two tubes on the left, collected at 0 and 2 h, lack clot formation. The two tubes on the right, collected at 5 and 10 h after antivenom treatment, show return of clot formation. Note continued bleeding from the fang wounds to the forearm

Fig. 40 The whole-blood clotting test is a simple bedside test to measure anticoagulation. Clean glass tubes are filled with 2–3 mL of blood and left undisturbed for 20 min, then gently inverted. Coagulopathy is present if there is absence of a clot, as shown by liquid unclotted blood flowing down the tube (*left* two tubes). Antivenom may produce a return of clotting function, with formation of a clear clot in the tube (*right* two tubes)

Fig. 39 Caregivers should be vigilant for evidence of systemic anticoagulation, as occurred in this critically envenomed *Echis* bite. Note gingival bleeding after field intubation

The venom of *Trimeresurus* and *Protobothrops* vipers also varies among species and within species from different regions. Several species, *P. flavoviridis*, *Trimeresurus gramineus*, and *P. mucrosquamatus*, contain high concentrations of metalloproteinases with hemorrhagin activity [57, 60–62]. The physiologic activity of the hemorrhagins, notably their attack on the walls of blood vessels [63], is shown clinically with extensive swelling and ecchymosis at the bite

Fig. 41 Russell's viper bite with local necrosis, partially healing (Myanmar)

site. Systemic bleeding is more common in children than in adults. *P. flavoviridis* venom also contains a phospholipase A₂ myotoxin [64], which is a likely cause of myoglobinuria observed in patients envenomed by this species. Investigation has shown that the venom of the far eastern habu species possesses venom antigen with unusual activity. *Protobothrops elegans* (Sakishima-habu) possesses a thrombin-like

Fig. 42 Russell's viper bite with extensive severe local necrosis. This will progress to a long term functional deficit, if the patient survives (Myanmar)

Fig. 43 Bilateral bruising of arms, distant to bite site, as a result of systemic coagulopathy following a Russell's viper bite (Myanmar)

enzyme, elegaxobin, which has potent activity against mammalian systems [65]. Investigation has shown that the venom of *Ovophis okinavensis* (Himehabu) possesses potent hemagglutinating activity [66]. In a hospital-based series of 29 patients envenomed by *Trimeresurus* (likely *T. albolabris*) in and around Bangkok, 46% of patients developed immediate pain, swelling that involved more than half of the limb, and regional tender lymphadenopathy [67]. Although bruising was observed in 58% of these patients, necrosis was seen in only two cases involving bites to the digits.

Elapidae

Asian elapids include the Asian cobras (*Naja*; Figs. 29, 30, 31, and 32), Asian coral snakes (*Calliophis*), king cobra (*Ophiophagus hannah*; Figs. 33 and 34), and kraits (*Bungarus*; Figs. 25, 26, 27, and 28). Sea snakes (previously Hydrophiidae) are specialized elapids found along Asia's tropical coasts.

The venoms of Asian elapids are well known for their neurotoxic and/or cytotoxic effects. These effects are mediated by presynaptic phospholipase A₂ neurotoxins, small postsynaptic peptide neurotoxins, and peptides that contribute to local tissue injury. Until recently there was no report of myotoxic effect from any Asian elapid venom. Generalized rhabdomyolysis has not been previously recognized as a feature of envenoming by any terrestrial Asian elapid snake, but recent cases suggest that venoms of some populations of *Bungarus candidus* and *Bungarus multicinctus* in Thailand and Vietnam and *Bungarus niger* in Bangladesh have this effect in human victims. A study reported edema and necrosis of extrafusal muscle fibers in envenomed rat soleus muscles confirming the myotoxic effect of *Bungarus niger* venom collected from snakes from Bangladesh, attributable to phospholipases A₂ [68].

Neurotoxins

Neurotoxicity manifested as acute neuromuscular paralysis is an important cause of morbidity and mortality related to Elapidae snakebite. The traditional view of snake venom neurotoxins causing only two types of neuromuscular blockade, presynaptic and postsynaptic, may be an oversimplified one and needs to be reviewed in view of the recent insights into neuromuscular transmission and descriptions of different patterns of neurotoxicity.

The presynaptically active neurotoxins (beta-neurotoxins (also known as β -bungarotoxin-type neurotoxins) – mostly neurotoxic phospholipase A₂ toxins, PLA₂s) target the motor nerve terminals (neuromuscular junction), specifically binding to the terminal axon, then entering the axon via endocytosis, then cause intracellular

Fig. 46 Extensive necrosis around the bite to a hand from a spitting cobra bite (Vietnam)

disruption of synaptosomes and synaptosome production. This causes synaptic ACh vesicles depletion, leading to impaired release of acetylcholine (ACh). The degeneration of the terminal axon intracellular structure can result in prolonged paralysis [69–72]. The resulting neuromuscular blockade occurs in three phases: an immediate depression of ACh release, followed by a period of enhanced ACh release, and then complete cessation of neuromuscular junction transmission due to lack of synaptic vesicles, following a latency period of 20–60 min [69, 73–78]. This binding of toxins to the nerve terminal is irreversible, resulting in a slow clinical recovery as it is dependent on regeneration of the nerve terminal and formation of a new neuromuscular junction. This seems to be the basis of patients requiring prolonged respiratory support after Krait bite. This also explains why treatment with antivenom or acetylcholinesterase inhibitors (AChEIs) is often unsatisfactory in presynaptic neurotoxicity, and incomplete recovery and delayed effects are more likely. Presynaptic toxins are best illustrated by beta-bungarotoxin (b-BuTX) of kraits (*Bungarus* spp.) which predominantly has potent PLA₂ enzymatic activity [79].

The postsynaptically active neurotoxins (alpha-neurotoxins; also known as α -bungaotoxin-type neurotoxins) are found in Asian cobra venom (*Naja atra*, *N. kaouthia*), king cobra, and several kraits. They belong to

the group of “three-finger toxins” (3FTXs), resembling three outstretched fingers of a hand and characterized by a shared toxin structure. They bind to the postsynaptic muscle nicotinic acetylcholine receptors (nAChRs). The postsynaptic neurotoxins are small, which likely explains their fast onset of activity. Postsynaptic toxins are classified into three groups: long-chain, short-chain, and nonconventional alpha-neurotoxins. “Short” peptides (<62 amino acids) are found in the cobras, and “long” toxins (70 amino acids) are found in the venom of king cobras and several kraits. Postsynaptic neurotoxins are the major constituents of the venom of many Asian cobras (*Naja*) and the king cobra (*Ophiophagus*) [80]. They are called “curare-mimetic”

neurotoxins due to their resemblance to the action of d-tubocurarine, a reversible, nondepolarizing postsynaptic block by competitive inhibition of ACh binding to the muscle nAChR [81]. The importance of this finding is that even profoundly paralyzed patients, such as patients requiring ventilator support, may recover quickly after treatment with appropriate antivenom. However, it has also been shown to inhibit the presynaptic neuronal nAChRs, producing the characteristic TOF or tetanic fade. Most of the long-chain 3FTXs such as alpha-bungarotoxin, however, bind almost irreversibly to the postsynaptic nAChRs, therefore, are not so readily reversible by antivenom or AChEIs. The clinician’s familiarity with the venom of the offending snake plays

Fig. 48 Developing local necrosis following a cobra bite

Fig. 49 Partial ptosis due to developing flaccid neurotoxic paralysis

a central role in differentiating paralytic cases that would respond to antivenom from cases in which antivenom stockpiles would be squandered.

Local Toxins

The venoms of Asian cobras also contain destructive polypeptides implicated in tissue necrosis. With the exception of kraits and one cobra species

discussed subsequently, envenoming bites from all Asian cobras (*Naja*) and the king cobra (*Ophiophagus*) are distinguished from nonenvenoming bites by the onset of local pain and minimal-to-moderate swelling. In contrast, the venom of the Philippine cobra (*Naja philippinensis*), all kraits (*Bungarus*), and Asian coral snakes (*Calliophis*) produces minimal local symptoms but often causes severe neurotoxic morbidity. Bites by these species may go unnoticed or be dismissed as nonenvenoming because of the paucity of local symptoms. Victims, usually farmers, frequently give the history of being bitten while sleeping in the rice field at night and waking up in the morning with weakness, not remembering any bite event. It may be that the victim had rolled onto questing kraits, resulting in a defensive bite. The krait bite may be painless and may not wake the farmer. The first evidence of envenoming may be ptosis or ophthalmoplegia when the farmer awakes the next morning. Occasionally, field biologists incorrectly identify a juvenile krait or Asian coral snake as a harmless species or dismiss any bites received as nonenvenoming, with tragic consequences.

Clinical Presentation

Several points may be made regarding the clinical presentation of patients envenomed by Asian elapids:

1. All elapid venoms possess some degree of neurotoxin; however, envenoming by cobras is often associated with local symptoms and local tissue damage, and this may dominate the clinical picture (Figs. 47, 48, 49a–c).
2. Envenoming by the Philippine cobra, all kraits, and coral snakes may result in minimal local symptoms but may cause life-threatening paralysis.
3. Envenoming by most cobras (*Naja*) (except for *N. philippinensis*) and the king cobra (*Ophiophagus hannah*) results in pain, swelling, discoloration, and necrosis.
4. Neurotoxic symptoms may appear quickly or be delayed more than 18 h.
5. Asian elapid venoms are not associated with coagulopathy, though a single study of

common cobra (*Naja naja*) bites in Sri Lanka noted three patients had a positive bedside test for coagulopathy (20WBCT) without any clinical evidence of bleeding [82].

An understanding of neurotoxic effects allows the physician to recognize severe cases and anticipate the need for advanced medical resources. The earliest symptoms suggesting envenoming by neurotoxic species, which may be delayed for hours, include tingling or aching sensation and occasional fasciculations in the bitten extremity.

The earliest symptom of systemic envenoming is repeated vomiting, but frequent use of emetics/herbals by the patient or “traditional healers” makes the interpretation difficult. Other early

preparalytic symptoms include contraction of the frontalis muscle (deliberate attempt by patient to overcome the ensuing ptosis), blurred vision and loss of visual accommodation (due to mydriasis), perioral paraesthesiae, hyperacusis, loss of the senses of smell and taste, headache, dizziness, vertigo and hypersalivation, congested conjunctivae, and piloerection (“goose-flesh”) due to autonomic stimulation. Patients with systemic envenoming may complain of headache, malaise, generalized myalgia, and may be restless. Paralysis usually starts as ptosis and progresses to external ophthalmoplegia, as ocular muscles are most sensitive to neuromuscular blockade (Figs. 37, 50, 51). Ptosis can be carefully diagnosed by formally assessing the lid retraction during upward gaze as tiredness may cause drooping eyelids. Signs of neurotoxicity may appear as early as 15 min after the bite (cobras) but may be delayed for 10 h or more following krait bites. Then a descending paralysis ensues involving the facial muscles, palate, jaws, tongue, vocal cords, neck muscles (“Broken neck” sign Fig. 51), and muscles of deglutition. Speech becomes muffled and indistinct. Many patients are unable to open their mouths, but in some cases, unable to close. Paralysis of pharyngeal muscles and muscles of deglutition put the patients in danger of aspiration or airway blockade. Respiratory arrest may be precipitated by obstruction of the upper airway by the paralyzed tongue or inhaled vomitus. Interco-

muscles may be affected before the limbs, diaphragm, and superficial muscles, and the pattern of breathing becomes abdominal or paradoxical (protrusion of the abdomen during inspiration). Patients with hypoxemia due to respiratory paralysis may present with impaired consciousness and generalized convulsions. However, drowsiness, before the development of significant paralysis, has often been described (attributed to endorphin) but remains unexplained. Intractable hypotension can occur in patients envenomed by Asian cobras.

despite adequate respiratory support. Neurotoxic effects are completely reversible, either acutely in response to antivenom or (for example in Asian cobras) to anticholinesterases [83–86], or they may slowly wear off spontaneously [87, 88]. There are examples of patients, supported by mechanical ventilators, recovering sufficient diaphragmatic movement to breathe adequately in 1–4 days; ocular muscles recover in 2–4 days, and there is usually full recovery of motor function in 3–7 days in the absence of specific

antivenom. However, especially in the absence of antivenom treatment, paralysis may persist. Patients have recovered after 30 days of manual ventilation (in a case of envenoming by the Chinese krait, *B. multicinctus*).

Patients requiring prolonged mechanical ventilation may tie up valuable ventilators, resulting in interruption of surgical and obstetric services. In austere medical settings, patients often develop iatrogenic complications as a result of a lack of skilled nursing care; clinical laboratory monitoring, in particular, blood gas analysis of ventilated patients; or adequate enteral feeding.

Asian Cobras (*Naja* Species)

Cobras are ubiquitous throughout tropical Asia (Figs. 29, 30, 31, and 32). The combined factors of high fecundity, toxic venom, tolerance of human activity, and close association with rice fields make cobras one of the leading causes of snakebite fatalities worldwide. The spectrum of local and neurotoxic symptoms seen in cobra envenoming is highly variable. Many cobra bites, 45% in one study [89], are nonenvenoming. Cobra venom contains fewer enzymes, compared with the venom of vipers; however, several venoms contain cofactors that enhance migration in tissue. *N. naja* venom contains nerve growth factor, which, as implied, stimulates the growth of mammalian nerve tissue [90] but also induces degranulation of mast cells. The resulting release of histamine and proinflammatory chemokines induces vasodilation. *N. naja* venom also contains cobra-venom factor, a glycoprotein that cleaves complement into the cytokine-inducing anaphylatoxins C3a and C5a [91, 92]. The venom of several species contains varying concentrations of unique polypeptide cytotoxins, which are implicated in local tissue injury. The bites of several Asian cobras (*N. sumatrana*, *N. kaouthia*, *N. atra*) can cause significant tissue destruction (Figs. 47, 48 and 49a–c), which may equal that seen after envenoming by Malayan pit vipers. In one series of 47 patients envenomed by *Naja* spp., 44% developed local necrosis, and 12% showed signs of neurotoxicity [89]. Laboratory studies indicate that the venom of several *N. naja* species possesses a nonenzymatic

cardiotoxin that exacerbates platelet aggregation by adenosine diphosphate and thrombin activation [93]. Despite seemingly well-designed laboratory studies, procoagulant and anticoagulant activity is not observed in envenomed patients.

In India, most cobra bites are caused by *N. naja naja* (Indian spectacled cobra; Fig. 30) [94]. In Bangladesh, Malaysia, and Thailand, most cobra bites are caused by *N. kaouthia* (Monocellate cobra; Fig. 29) [53, 89] with rice farmers and aquaculturists being the most common victims [95].

Patients envenomed by *N. kaouthia*, *N. atra*, and *N. naja* and by bites by the smaller Asian spitting cobras (see later) experience immediate pain and aching at the bite site. In the first few hours, there is soft tissue swelling and discoloration of the skin. Four to 60 h after the bite, the tissue surrounding the fang marks becomes mottled and gray, and dependent migration of blistering is often observed (Fig. 49a–c). The first systemic symptoms are drowsiness, nausea, vomiting, and ptosis. In one case, neurotoxicity developed within 30 min of the bite [96]; however, symptoms usually are delayed more than 3 h and may appear 20 h after envenoming. The delay in neurotoxicity likely reflects the time required for the neurotoxin to reach the neuromuscular junction. In children, the earliest and most common evidence of neurotoxicity after cobra bites is ptosis, drowsiness, and inability to keep the head upright [96].

Asian Spitting Cobras

Many Asian cobras defend themselves by spitting fine droplets of venom into the eyes and mucous membranes of animals, resulting in severe contact ophthalmia. The species most frequently implicated in “spitting” venom injury are the Thai spitting cobra (*Naja siamensis*; figure 31), the Javan cobra (*Naja sputatrix*), the Malay-Sumatran spitting cobra (*N. sumatrana*) [89], and the Sumar cobra (*Naja sumarensis*). There is limited evidence that some *Naja kaouthia* from the West Bengal region can spit venom, but it is unclear if this has occurred in human patients (Julian White, Personal Communication.). It is suggested that spitting cobras have the ability to target the eyes

of the offending animal. Spitting cobras can spit venom 2 m or more; however, as the twin venom streams travel toward the target, the streams degrade into an aerosol of fine droplets. Venom ophthalmia develops when this venom comes in contact with the eyes resulting in immediate pain and swelling. Within minutes, the victim experiences conjunctival and palpebral edema, blepharospasm, and leucorrhea. In African species, the venom of similar species may traverse the conjunctiva and enter the lymphatics, resulting in paralysis of the facial nerve [97]. There is no evidence that local spat venom can be absorbed and cause systemic envenoming. Corneal erosions and secondary infection are reported after spit venom injury from several African species (ringhals). Venom sprayed onto oral and nasal mucous membranes results in tingling sensation followed by irritation, which quickly escalates in severity. The bites of Asian spitting cobras may cause local pain, swelling, blistering, and necrosis, which may be severe. While the venom may contain neurotoxins, paralytic envenoming is unlikely following spitting cobra bite, though should always be tested for, both on initial presentation and over subsequent hours of observation.

King Cobra (*Ophiophagus Hannah*)

The king cobra (*O. hannah*; Fig. 33) is the world's longest venomous snake, with documented lengths greater than 5 m. The species has an extensive range, from western India to southern China, Malaysia, Indonesia, and the Philippines (Fig. 34) [98]. The species is brown green in India, olive green throughout most of Southeast Asia, and dull yellow on Mindoro and Negros islands. King cobras are obligate reptile predators that prey almost exclusively on other snakes, including venomous species. The species are highly evolved and are among the minority of snakes known to construct nests and to defend the eggs. This behavior may explain the reputation for aggressiveness and accounts of "unprovoked" attacks on humans. During field collection, king cobras seem more intent on escape and defend themselves only when restrained by the snake hook or when cornered. Specimens quickly acclimate to captivity, becoming tolerant of humans, and quickly learn that

human activity near the cage indicates the likelihood of a meal. Many bites involving captive animals occur when snakes and snake handlers lose their fear of each other.

King cobras can deliver large amounts of venom through fixed fangs, which may exceed 9 mm in length. During venom extraction procedures, 1200 μ L of venom may be obtained from a single 4-m long specimen. The venom is composed primarily of heterogeneous postsynaptic neurotoxins, and deaths usually result from respiratory paralysis. Locally active toxins include hyaluronidase; cobra-venom factor; hannahtoxin, an enzyme with hemorrhagin-like activity; and a unique protein toxin with multiple activities [99]. These factors likely explain the ecchymosis and swelling observed in the envenomed extremity. The presence of local symptoms should alert the physician to the probability of systemic envenoming. The case-fatality rate in king cobra envenoming is high. In a Myanmar series [100], 22 of 35 (63%) bitten patients died, and in a Chinese series [59], 7 of 13 (54%) bitten patients died. Antivenom treatment of severe bites may require many vials. Little quality research has been performed on the variability of venom from king cobras from different regions.

Kraits (*Bungarus*)

Kraits are highly venomous snakes of the genus *Bungarus*, Family Elapidae (Figs. 25, 26, and 27). Kraits are a widely distributed group of snake-eating species that are found throughout the South and East Asian region (Fig. 28). Inhabiting Southeast Asia, southern China, Indonesia, and the Indian subcontinent, they feed primarily on lizards and other snakes. Many species are reportedly docile during the day but become fast moving and more prone to bite at night. In general, they tend to be slender snakes, and similar to other elapids, they have relatively short fangs mounted on the anterior maxilla. Kraits can be found at altitudes ranging from sea level to 1600 m above, and they often inhabit lowland forest terrain. In many parts of India, Bangladesh, Sri Lanka, and Myanmar, humans often are bitten while sleeping in the fields or on the floors of huts. Interestingly, in Myanmar, kraits are

welcomed by rural villagers who know they kill and eat other venomous snakes, such as Russell's viper, which overall are perceived as presenting a higher risk (Julian White, Personal communication).

Seven of 15 krait species have been implicated in human envenoming, and each of these species possesses venom with presynaptic neurotoxins. In several regions, kraits rival the cobras as the leading cause of snakebite-related fatalities [101, 102]. Although they are not considered aggressive snakes, and the reported incidence of bites is relatively low, all species should be considered capable of delivering a potentially lethal envenomation. Kraits deserve special mention due to the burden that krait-bite paralysis places on ICU resources, particularly in rural hospitals.

Bungarus caeruleus, also called the *common Indian krait*, is a relatively uncommon cause of envenomation in India, Pakistan, Bangladesh, Nepal, and Sri Lanka (Fig. 26). With mortality rates for envenoming untreated with antivenom of 77–100% [101, 102], *B. caeruleus* is considered one of the most dangerous snakes in the Indian subcontinent.

Bungarus multicinctus, the *Chinese* or *many-banded krait*, is similar to *B. candidus* (its sister species), but distributed from northern Laos/northern Vietnam north across southern China and into Taiwan. Together with *Naja atra*, the clinico-epidemiologically most important elapid snake in this region, *B. multicinctus* accounts for roughly 8% of all snakebites in China and Taiwan. The venom of this species is included in AV production in Taiwan and China, also attempted in Vietnam. Clinically they produce “typical” *Bungarus* envenoming with recent reports suggesting natriuretic effects and permanent damage to the eye (persisting mydriasis) in northern Vietnam. Mortality rates were 10% and 23% in two case series [59, 103].

Bungarus candidus, also called the *Malayan krait* (Fig. 25), can be found from Thailand, Laos, Cambodia, southern Vietnam south through West Malaysia into Indonesia (on Sumatra, Java, Bali) and has been identified as a major cause of snakebite mortality in Thailand and southern Vietnam. It was recently included in AV production by

QSMI/Thai Red Cross Society. Clinically it causes “typical” krait envenoming with recent reports suggesting myotoxicity/myoglobinuria in some cases (Thailand/Vietnam). In a case series of five patients bitten by this snake, only one patient died, and two patients never developed any signs or symptoms of envenomation [84].

Bungarus fasciatus, also known as the *Asian banded krait* (Fig. 27), is found from eastern Indian states to southern China and south through West and East Malaysia into Indonesia (on Sumatra, Java, Borneo). It is very common regionally and often seen by humans but rarely implicated in envenoming bites. It is an uncommon but significant cause of snake envenomation in China. In mice the venom is about 10 times less toxic than that of other kraits, but venom yield is also much higher than that of other kraits (probably also by a factor of 10). Severe and fatal envenoming has been reported. It is included in AV production in Thailand (also China, Indonesia). It eats other snakes including kraits, cobras and viperids. In parts of India and Myanmar, its presence around the village and in the field is regarded as a sign of luck because people know about its feeding habits and claim that its presence will reduce the number of “dangerous” snakes (by eating them and by other snakes fearing the smell of *B. fasciatus*). It is very sluggish and reluctant to bite during the day. One study reported a 7.7% mortality rate [59], whereas another study reported two of four bitten patients dying from systemic envenomation [104].

Bungarus flaviceps occurs commonly in southernmost Vietnam, southern Myanmar and Thailand, West and East Malaysia, and parts of Indonesia (Sumatra and Borneo only). This is a very docile and shy snake, living only in undisturbed primary rainforest. There are no bites on record where the snakes naturally occur. The venom contains toxins of the same toxin families as other Kraits (e.g., beta-bugarotoxins, kappa-bungarotoxins characterized, others like alpha-neurotoxins are likely also present based on mass spectrometry).

It is important to identify patients who are bitten by kraits because they may present before the onset of significant symptoms, when antivenom would be more effective. Early recognition

of krait bites provides a crucial opportunity to make maximal use of antivenom resources and intervene in the progression of paralysis. Such efforts are advantageous for health clinics located in remote settings because they allow critical ICU resources, such as ventilators, to be conserved for other patients. Local symptoms warning of krait envenoming include numbness, paresthesias, mild discomfort, and aching of extremity muscles. Ecchymosis is not likely with most krait bites. Kraits are not expected to cause coagulopathy. Envenoming by several species (e.g., *Bungarus caeruleus*, *Bungarus candidus*) may be associated with abdominal discomfort [88]. Many patients report generalized muscle pain within hours of the bite. Laboratory evidence of envenoming is restricted to modest elevations of plasma myoglobin and marked neutrophil leukocytosis [41, 102], although hyponatremia has also been reported.

Sea Snakes

Sea snakes are highly venomous and inhabit tropical waters of the Indian and Pacific Oceans, from the Persian Gulf eastwards through Sri Lanka to Southeast Asia, and the southwest Pacific, along the northern coast of Australia and north to the southern islands of Japan [105, 106]. *Enhydrina schistosa* (*Hydrophis schistosus*) is one of the most clinically important species; it lives in the coastal waters, lagoons, river mouths, and estuaries. It is considered as one of the most aggressive sea snakes. Other important species include some other *Hydrophis* spp., *Lapemis curtus*, *Pelamis platurus*, and *Laticauda colubrina*.

There is a lack of epidemiological data concerning sea snakebite in most regions, apart from occasional case reports. Victims of sea snakebites are often treated by traditional healers and fatalities are not reported to the health authority. Majority of sea snakebites (68%) could be dry bites [107]. Another analysis documented that a significant envenoming occurs in about 20% of cases, and deaths occur in about 3% of all bites [108].

Venomous sea snakes have flattened paddle-like tails, and their ventral (belly) scales are greatly reduced in size or lost.

Generalized rhabdomyolysis with consequent gross myoglobinuria, high creatine kinase (CK) levels, and hyperkalemia and neurotoxicity resulting in respiratory muscle paralysis are the main features, although patients without this feature have been described. Electromyographic recordings showed myopathic features.

Envenoming by sea snakes (“Hydrophiinae”) and sea kraits (“Laticaudinae”): the bite is often painless with minimal or no local swelling and the wader or swimmer may not even notice it. Involvement of local lymph nodes is unusual. Features usually appear between 30 min and 3½ h after the bite. In the early stage, patients may complain of headache, a thick feeling of the tongue, thirst, along with sweating and vomiting. Later features of myotoxicity such as generalized aching, stiffness and tenderness of the muscles, and painful passive muscle stretching become noticeable. Trismus may be present. These are followed by progressive flaccid paralysis starting with ptosis. The patient remains conscious until respiratory failure develops due to involvement of respiratory muscles. Myoglobinemia and myoglobinuria are suspected when the serum/plasma becomes brownish and urine becomes dark reddish brown (“Coca Cola colored”). Bedside “stix” tests give a positive result for hemoglobin/blood in urine containing myoglobin. Acute kidney injury may ensue due to myoglobin and potassium released from damaged skeletal muscles. Hyperkalemia (may develop 6–12 h of the bite) may also precipitate cardiac arrest and should be managed promptly.

Not all sea snakebites present with myotoxic envenoming; in some cases, there appears to be pure neurotoxic paralysis, following the classic features and progress of flaccid descending paralysis, as noted earlier for other primary neurotoxic species such as kraits.

Colubridae

As noted earlier, the previous taxonomy of snakes that placed most species in a single Family, Colubridae, has been more recently superseded and a new term, non-front-fanged-colubrids developed, to cover the wide variability in toxin

production and venom delivery mechanisms. Thus, those NFFC snakes currently known to cause potentially significant envenoming effects in humans, and previously all placed in Family Colubridae, now are found across several snake families (see Table 1, earlier in this chapter). The secretions of Duvernoy's gland of several NFFC snakes are capable of producing envenoming injuries. Currently recognized physiologic effects include defibrination and disseminated intravascular coagulation-like reactions, generalized protease activity, phosphodiesterase activity, and phospholipase A₂ activity [109]. Although bites of many species produce local reactions, this discussion focuses on the two Asian NFFC snakes implicated in severe envenoming or fatalities.

Rhabdophis tigrinus (Japanese yamakagashi) and *Rhabdophis subminiatus* (Asian red-necked keelback; Figs. 35 and 36), both in Family Natricidae, are slender, fast-moving snakes that are common in many regions. Bites by *R. subminiatus* are rare throughout the species' range of Thailand, Laos, Myanmar, and Malaysia; however, imported specimens have caused fatal envenoming in several Western countries [110–112]. Lacking canaliculated fangs, the *Rhabdophis* spp. must introduce venom into puncture wounds made by a fixed pair of posterior-positioned maxillary teeth. Envenoming injuries usually involve the snake's hanging on and chewing on the patient. Local findings are distinctive for the absence of anterior fang marks. The local effects of venom may be minimal. Initial symptoms start 1–9 h postbite and include nausea, vomiting, gastrointestinal discomfort, and headache. Onset of coagulopathy is indicated by return of bleeding from the teeth marks. The patient's blood may become incoagulable within hours and may cause gingival bleeding, epistaxis, hematemesis, melena, subarachnoid and intracerebral bleeding, hematuria, and extensive echymosis. Laboratory studies show defibrination, with elevated degradation products, thrombocytopenia, and schistocytes appearing on a peripheral blood smear, suggesting a microangiopathic hemolytic process [113].

Envenoming by the Japanese yamakagashi, *R. tigrinus*, is more common and more severe than envenoming by *R. subminiatus*. Local reactions include swelling, which may involve the entire extremity. Coagulopathy may be severe, leading to intracranial hemorrhage [111]. In addition to severe coagulopathy, envenoming by *R. tigrinus* can cause renal failure, with postmortem studies showing acute tubular necrosis [110]. Antivenom is available for *R. tigrinus* (see Table 9).

There are reports of other species causing systemic envenoming such as *Balanophis ceylonicus* (Sri Lankan keelback) [114], or local envenoming such as *Boiga dendrophila* (mangrove snake) [115] and some other *Boiga* species (cat snakes); *Ahaetulla nasuta* (long-nosed whip snake); *Cerberus rhynchops* (dog-faced water snake); *Enhydryn enhydryn* (rainbow water snake).

Management of Snakebite

In many parts of rural Asia, patient transport to a medical facility often is delayed hours to days. Initial treatment by community health clinics encountered along the way may be rudimentary, may be inaccurate, or may result in injurious treatment. In recent years cellular phone networks have expanded into many of Asia's rural regions, allowing physicians to be notified of inbound emergencies. Prehospital communication also allows physicians to guide bystanders in obtaining basic vital signs, to counsel against injurious attempts at first aid, to measure for changes in swelling, and to observe for evidence of coagulopathy or neurotoxicity. By extending assessment into the prehospital period, the physician may determine the severity of symptoms and prepare in advance for the care for the patient (e.g., IV fluid, antivenom, ventilators, dialysis). In Western countries, a case of exotic snakebite invariably generates considerable interest among hospital staff – which does not translate into better medical care. In these different treatment environments, the gravity of the situation is the same: *Snake envenoming is a medical emergency until proved otherwise*. The time before the patient's

arrival should be used to identify the treatment team, notify the laboratory, identify local snake experts, acquaint medical staff with management priorities and pitfalls, and transport antivenom to the treatment center.

Steps in Management of snakebite [116]

- First aid treatment
- Transport to hospital
- Rapid clinical assessment and resuscitation
- Detailed clinical assessment and species diagnosis
- Investigations/laboratory tests
- Antivenom treatment
- Observing the response to antivenom
- Deciding whether further dose(s) of antivenom are needed
- Supportive/ancillary treatment
- Treatment of the bitten part
- Rehabilitation
- Treatment of chronic complications

First Aid Treatment

Principles of First Aid

The physician should be familiar with first aid measures for snakebite because he or she may need to make optimal use of these techniques while waiting for the arrival of antivenom or may need to address complications resulting from well-intentioned but damaging first aid. In resource-rich countries, first aid rarely is applied in the hospital setting. In Asia, rural medical clinics often can offer little to the patient except first aid. In this circumstance, simple procedures and precautions may benefit the patient by delaying the spread of venom until the patient reaches a hospital. First aid for snakebite in Asia is summarized in Table 3.

1. Reassurance: Snakebite is an unexpected dreadful event. The victim becomes apprehensive of the unknown outcome and is often terrified. Many of the initial features after a bite are caused by sympathetic drive due to overwhelming fear. This may obscure or mimic signs of envenomation, so it is very important to provide reassurance and to try to make the patient calm.

Table 3 First aid for Asian snakebite

ABCs: Place patient in the lateral recumbent position. If nonbreathing, insert an oral airway or pull tongue forward. Perform rescue breathing if necessary. If hypotensive, raise extremities, or use pneumatic antishock garments
Do no harm
Transport promptly to a hospital
If patient is alert, place patient at rest and provide reassurance
Wash bite wound to remove unabsorbed venom
Delay the spread of venom by keeping the patient as still as possible and immobilize the bitten extremity in a functional position at or below heart level
Remove rings, watches, and other potentially constrictive items
Painkillers, especially narcotic analgesia and NSAIDs, should not be used except at the recommendation of a physician familiar with snake envenoming
NSAIDs nonsteroidal anti-inflammatory drugs

- 2. As with any other situation, the golden rule for first aid after snakebite is “Do No Harm.” Do not tamper with the bite wound in any way, but immobilize the bitten limb using a splint or sling. If the patient is thought to have been bitten by a dangerously neurotoxic elapid snake (including sea snakes), consider pressure immobilization (see below).
- 3. Arguably the best thing that can be done for a snakebite victim is to transport them to a health care facility as quickly as possible. The ideal should be whole patient immobilization, but especially immobilization of the bitten limb, as any muscular contractions will promote spread of venom. Ideally, the patient should be transported by motor vehicle, bicycle (as a passenger), boat or on a stretcher. The system of carrying the patient on the back of a motorcycle, sitting in between two other persons has proved effective and also been shown to improve outcome [117] in a developing nation resource poor setting.
- 4. Avoid harmful and time-wasting treatments. Examples of some harmful “treatments” commonly practiced are provided below.
- 5. The offending snake should be taken along to hospital with the patient, if it has already been killed, for species diagnosis. However, catching or killing the offending snake should never

be advocated. Searching for the snake will waste valuable time and it also includes risk of further bites. Caught alive or even once dead, the snake should be handled with extreme caution and preferably by someone with experience. Snakes which appear to be dead should not be touched with the bare hands but carried in a bag or dangling across a stick. Some species (e.g., *Hemachatus haemachatus*) sham death, and even a severed head can inject venom.

Rejected or Controversial First Aid Methods

Traditional treatments are popular and widely used by people not only in rural regions in developing countries but also in some parts of the developed/western world.

These may include tight tourniquets, constriction bands, wound cauterization, incision or excision, amputation of the bitten digit, suction by mouth, vacuum pumps or “venom-ex” apparatus, instillation of chemical compounds such as potassium permanganate, application of ice packs (cryotherapy), “snake stones,” electric shocks, and many others [118]. These have no proven benefit and are discouraged [119].

In a patient with coagulopathy, incisions can cause uncontrolled bleeding. This may also inflict damage to nerves, blood vessels, or tendons and can cause secondary infection. Tissue necrosis may result from suction, application of chemicals, and cryotherapy.

Dangers of Tight Tourniquets

Tight arterial tourniquets applied for prolonged periods are known to cause necrosis resulting in loss of function and even part of an extremity. These may cause congestion, swelling leading to ischemia and gangrene, if they are applied for more than about 2 h. They can also directly damage peripheral nerves (e.g., the lateral popliteal nerve when pressed against the neck of the fibula). Increased bleeding may result from increased fibrinolytic activity. Local effects of venom may be pronounced. On the other hand, rapid development of life-threatening systemic envenoming or even pulmonary embolism may ensue after their release [120].

Pressure Immobilization

The splinting and crepe bandaging method (“pressure bandage and immobilization”; PBI) developed in Australia proved effective in limiting the absorption of Australian elapid toxins in animal experiments. The applicability of this method in a real-time setting has been questioned, with only 18–50% of the bandages in place and effective at arrival at hospital. Crepe bandaging is thought to exert a pressure of about 55 mmHg. Obstruction of lymphatic and venous drainage delays systemic absorption of large molecular-weight neurotoxins without the use of tight tourniquets, which are dangerous. However, it is difficult to apply PBI unaided and to judge the pressure applied. Any sort of external compression may increase the intracompartmental pressure and may worsen the effects of necrotic snake venoms, specifically vipers (Table 4; contraindications for use of PBI). This may not be appropriate for all cases of snakebite [120, 121]. An alternative and simpler method of application of a foam rubber pad directly over the bite wound delayed systemic envenoming, as assessed by measurements of venom antigenemia and the method appeared safe and effective in a field trial in Myanmar [122]. This has been the recommended first aid for snakebite in Myanmar for many years.

Considering the ability to delay the spread of venom and development of early respiratory paralysis, the PBI technique should be applied if

Table 4 Contraindications to pressure bandage immobilization

Bite by unknown species with local evidence of tissue damage
Any bite with pain, swelling, and bleeding from fang marks
Bites associated with severe coagulopathy
Bites >24 h, without symptoms
Bites by NFFC snakes (e.g., <i>Boiga</i> , <i>Rhabdophis</i>)
Bite by any Asian viper or pit viper (possible exception: <i>Daboia r. russelii</i> in southern India and Sri Lanka)
Any cobra bite with local pain, swelling, or significant discoloration

Comment: Pressure-immobilization bandages seem beneficial for envenoming by kraits, Asian coral snakes (*Calliopus*), king cobra (*Ophiophagus hannah*), and Philippine cobra (*Naja philippinensis*)

a bite by a neurotoxic elapid cannot be excluded. The bitten limb should be bandaged at a pressure of about 50–70 mmHg and immobilized with a splint (pressure immobilization), or a pressure pad should be applied at the site of the bite. It is very important to restrain the patient from walking or moving or using other limbs as movement of the other limbs may increase spread of venom. Patient should lie down and be carried on stretcher or kept as immobile as possible [119].

Management of Early Effects Before the Patient Reaches the Hospital

Diverse manifestations of envenoming may appear before the patient reaches hospital. These should be assessed and managed promptly and correctly, as these may dictate the outcome for the patient later on.

Local pain: one of the commonest symptoms and may be severe. Nonsteroidal anti-inflammatory agents, which carry the risk of gastric bleeding in patients with incoagulable blood, should be avoided. Oral paracetamol (acetaminophen) is preferable. Severe pain should be treated with opiates, but caution if there is a possibility of envenoming causing respiratory depression or compromise.

Vomiting: is a common early symptom of systemic envenoming. Persistent vomiting can be treated with intravenous chlorpromazine (25–50 mg in adults, 1 mg/kg in children). In patients with altered consciousness there is the additional problem of aspiration. Patients should be maintained in the recovery position (on their left side).

Syncopal attacks and anaphylactic shock: this may occur immediately within minutes of bite. This is usually due to either a vasovagal attack with profound bradycardia or due to anaphylaxis with angioedema, urticaria, asthma, abdominal colic, and diarrhea. Anaphylaxis is a medical emergency and should be treated promptly with adrenaline 0.1% (1 in 1000) (0.5 ml in adults, 0.01 ml/kg in children) by intramuscular injection followed by a histamine H1-blocker such as chlorpheniramine maleate (10 mg in adults, 0.2 mg/kg in children) which can be given by intravenous or intramuscular injection. In patients with coagulopathy, pressure dressings should be

applied to all injection sites to prevent oozing and decrease the chance of hematoma.

Respiratory distress: usually caused by weakness or paralysis of respiratory muscles but may also be the result of inability to maintain patent upper airway due to jaw, tongue, and bulbar muscle paralysis. The airway should be quickly cleared, if possible using a suction pump, an oral airway should be inserted and the jaw should be elevated, and patients should be placed in the recovery position. Oxygen should be given to patients with cyanosis, or if respiratory movements are weak. There should be a low threshold for initiation of assisted ventilation. If clearing the airway does not produce immediate relief, artificial ventilation must be initiated. Mouth-to-mouth or mouth-to-nose ventilation can be lifesaving if a mechanical ventilation facility is not available. The patient can be ventilated by manual ventilation with an Ambu bag and a cuffed endotracheal tube or a cuffed tracheostomy tube inserted. Ambu bag and anesthetic mask without an endotracheal tube are not very reliable. If no femoral or carotid pulse can be felt, external cardiac massage should be instituted.

Medical Treatment in the Hospital

Snakebite is a medical emergency. Depending on the time lapse between bite and reaching hospital, patients may show early or late signs of envenoming or its complications. Direct cardiovascular effects of the venom (e.g. *Daboia russelii*, *D. siamensis*); blood loss, persistent vomiting, or other causes of dehydration; activation/inhibition of physiological vasomotor systems (such as the angiotensin-renin-bradykinin systems) by venom toxins; and anaphylaxis due to antivenom given outside hospital and rarely, provoked by venom in sensitized habitual snake handlers by previous exposure. All of these may produce sudden profound hypotension and shock in a severely envenomed patient. In hospitalized patients, cardiac arrest may also result from hyperkalaemia in those with massive rhabdomyolysis after sea snakebites. If patients are not kept in a recovery position,

aspirated vomitus, a foreign body, or the fallen back tongue can cause blockage of the upper airway, especially in patients with evolving bulbar paralysis.

The history, symptoms, and signs of the patient with a history of snakebite should be assessed quickly. Airway, breathing, and circulation must be checked immediately. Vital signs (blood pressure, pulse rate, and respiratory rate) must be recorded. Cardiopulmonary resuscitation including clearance of the airway, oxygen administration by facemask or nasal catheters, and establishment of intravenous access are among the first things to do. Choice of venous access should be considered; avoid vessels where the risk of major bleeding is increased or difficult to control (subclavian, femoral, jugular) if at all possible. A timely resuscitation may salvage a moribund patient.

Physicians and other health care professionals should be very careful during removal of tourniquets, bands, or ligatures. There may be sudden deterioration of clinical condition after release, resulting in shock, bleeding, or respiratory paralysis [123]. Antivenom treatment should be initiated and appropriate staff and resuscitation equipment should be on hand.

History and Examination in Hospital

When in hospital each patient should be asked about the site of bite, time of bite, how many times bitten, or if the snake is brought along? If the snake is not brought, then efforts should be made to collect it, if it has already been killed. Patients/attendants should be asked in detail about the events following the snakebite: vomiting, abdominal pain, dizziness, bleeding, or any uneasiness after the bite. Any drugs or alcohol taken should be noted. Ask the patient about presence, rate of development, and progression of any symptoms and whether they have passed urine since being bitten. Table 5 summarizes important data to obtain from the patient history.

Initial symptoms may be nonspecific or attributed to other causes, such as traditional remedies (e.g., use of kava, opiates, or emetics) or fatigue or dehydration after prolonged transport. In many parts of rural Asia, the snakebite victim first

Table 5 Patient history

All cases
Name, age, weight of victim
Size, color, shape, and distinctive features of the snake (see Figs. 1–3, 5–7, 9, 11, 13–15, 17, 19, 21, 23, 25–27, 29–31, 33, 35)
Time bite occurred
Geographic location where bite occurred (swamp, forest, zoo)
Anatomic location of bites and number of bites received
Initial symptoms, timing of onset postbite
Type of first aid or traditional therapy received
Past medical history (e.g., asthma)
Medication (prescription drugs such as β -blockers, anticoagulants, NSAIDs, nonprescription drugs, recreational drugs, alcohol)
Prior history of antivenom administration
Change in symptoms during transport
Presence of priority symptoms: nausea, vomiting, blurred vision, dizziness, dyspnea, syncope, weakness, chest pain, urinary retention, bleeding nares or gums, dark-colored urine, melena, hematochezia
Tetanus immunization status
For viper and Rhabdophis bites
Blood type
Recent surgery
History of cardiac disease, anemia, or hemoglobinopathy
For cobra, krait, and coral snakebites
Time of last meal
History of prior intubation
History of bronchospasm or bradyarrhythmias
Edrophonium hypersensitivity
Location of responsible family members (to assist in care of paralyzed patients)

seeks treatment from traditional healers, which may obscure local signs of envenoming. Patients often do not disclose use of traditional therapies, such as herbal remedies, elixirs, and ointments, which could complicate assessment and management. In Laos and West Vietnam, traditional healers may administer opiate-based powders, which can cause effects that suggest neurotoxic envenoming. Many traditional healers massage herbal compounds into the fang marks, potentially increasing the spread of venom and the risk of secondary infection. These activities also may increase the flow of bloody fluid from fang marks, suggesting coagulopathy.

The earliest symptoms suggesting neurotoxicity are tingling, numbness or dull ache in the extremity, vague abdominal discomfort, restlessness, anorexia to food and fluids, drowsiness, and blurred vision (due to ophthalmoplegia). Other symptoms suggesting systemic neurotoxicity are perioral fasciculations or paresthesias (in nonhyperventilating patients), metallic taste, and dizziness. In Asia, the use of molecular detection or immunoassays for diagnosing envenoming so far has been confined to research trials.

All patients with suspected snakebite should be admitted for observation for at least 24 h even if there is no evidence of envenoming initially. Envenoming by the Philippine cobra, kraits, and coral snakes, all of which may cause insidious neurotoxicity, cannot be ruled out before 24 h of observation. This prolonged period of observation reflects experience with rare cases that present with symptoms 21 h after snakebite.

Clues That Suggest that a Patient May be Severely Envenomed

- 1. A definitely identified offending snake of a dangerously venomous species.
- 2. Early local lymphadenopathy.
- 3. Early symptoms of systemic envenoming: nausea, vomiting, abdominal pain, diarrhea, severe headache, restlessness, heaviness of the eyelids, pathological drowsiness or early ptosis/ophthalmoplegia, collapse (hypotension, shock).
- 4. Early spontaneous systemic bleeding (gums, nose, hematemesis, feces or urine), or persistent bite site/venipuncture site bleeding, dark brown/black urine.

Only if the snake can be identified confidently as non venomous can the patient be discharged after a booster dose of tetanus toxoid.

Physical Examination

Important points of the physical examination are summarized in Table 6. Patients should be evaluated very carefully before removal of any compression bandage or tourniquet. Although the presence of two or three discrete puncture marks

Table 6 Physical examination

Local and systemic examination
Vital signs: respiratory rate, blood pressure, heart rate
Presence of fang marks, bleeding, erythema, discoloration, ecchymosis, swelling, local pain; check for evidence of multiple bites
Distal pulses (capillary refill); monitor for compartment syndrome
Lymphangitis or tender draining lymph nodes
Presence of damaging first aid methods (e.g., incisions, burns, amputations, cryotherapy, electrical burns, tourniquets)
Presence of necrosis, putrefaction, myolysis, secondary infection
Systemic examination
Neurologic examination: Eye examination using finger count and cranial nerve examination, looking especially for even mild ptosis as an early marker for developing neurotoxicity. Assess motor strength and symmetry, and rule out respiratory abnormalities. Respiratory symptoms include dysphonia, dyspnea, use of accessory muscles of respiration, or decreasing peak expiratory flow (measured using a handheld device)
Coagulopathy: Evaluate for retinal and gingival hemorrhage; bleeding from nares or gastrointestinal tract; presence of petechiae or ecchymosis, particularly under elastic bands. Intracranial bleed should be ruled out with neurologic examination
Musculoskeletal examination: Evaluate for compartment syndrome. Palpate muscles for tenderness, which may suggest myolysis. Examine urine for color and presence of casts suggesting proximal tubular cells, hematuria, hemoglobinuria, or myoglobinuria

suggests a bite by a venomous snake, bite mark is not always dependable. Bite site swelling with tenderness and local lymphadenopathy are early signs of envenoming. Patients may be noticed attempting to overcome developing ptosis (raised eyebrows and puckered forehead due to contraction of the frontalis muscle; Fig. 50). Ophthalmoplegia may initially be intermittent, improving when the patient continues to focus on an object. In the case of envenoming by *Bungarus* spp., patients first lose fast saccade eye movements, followed by the development of diplopia. Complete ophthalmoplegia may be delayed many hours. Appearance of dyspnea, “paradoxical” abdominal respiration and cyanosis should alert the physician about impending respiratory failure.

Evidence of systemic coagulopathy may not be apparent at presentation. Early on, envenoming by Asian vipers may cause thrombotic events manifesting as transient cerebral ischemia, syncope, myocardial infarction, arrhythmias, and, rarely, pulseless extremities due to arterial thrombosis. At the time of presentation, most coagulopathies present as prolonged prothrombin time and activated partial thromboplastin time or as incoagulable blood. Coagulopathy usually is first apparent at the bite site, where fang and teeth marks may continue to bleed. Spontaneous hemorrhage from the gingival sulci, retinal hemorrhage, and hematuria or hemoglobinuria suggests incoagulable blood. The presence of incoagulable blood may be confirmed using several low-technology assays, such as the whole-blood clotting test (Figs. 38 and 40 with results in 20 min (20WBCT); Table 7).

The patient should be carefully examined to detect any bleeding from venipuncture sites, recent wounds or skin lesions, and the gums. The oral cavity should be examined as gingival sulci are usually the earliest site of spontaneous bleeding. If the patient is found in shock (collapsed, sweating, cold, cyanosed extremities, low blood pressure, tachycardia), the foot end of the bed should be raised, and an intravenous infusion of a plasma expander or fresh blood started immediately. The jugular or central venous pressure should be observed. Generalized

rhabdomyolysis may cause trismus and stiff and tender muscles. Urine output may decrease very early after Russell's viper bite. Dark (Coca Cola) urine suggests myoglobinuria or hemoglobinuria.

Patients should be followed up hourly for any new effects, level of consciousness, ptosis, pulse rate and rhythm, blood pressure, respiratory rate, extent of local swelling, and appearance of any other new sign. If there is any evidence of neurotoxicity or respiratory involvement, the ventilatory capacity or expiratory pressure (peak flow rate for a resource poor setting) should also be recorded every hour. Distal pulses and capillary refill should be checked periodically to ensure adequate peripheral perfusion and to provide an early warning of compartment syndromes.

A tourniquet or tight compression bandage may cause distal edema through venous congestion even in a nonenvenoming bite. A tightly applied ligature will prevent arterial supply and will cause a cold, pulseless, cyanosed extremity.

Pulseless extremities should undergo intracompartment manometry using a pressure transducer. Compartment syndromes in patients with coagulopathy pose a dilemma because fasciotomy performed under these conditions may result in severe hemorrhage. The use of "prophylactic" fasciotomy is absolutely contraindicated because true compartment syndromes from snakebite are rare.

Table 7 Bedside tests for coagulopathy

20 min Whole-blood clotting test (20WBCT)

Place 2 mL of freshly collected venous blood in a small, new or heat cleaned, dry, glass vessel

Leave undisturbed for 20 min at room temperature (>21 °C)

After 20 min, tip the vessel once

If the blood remains liquid (unclotted) and runs out, the patient has hypofibrinogenemia ("incoagulable blood") as a result of venom-induced consumption coagulopathy

In Asian snakebite cases incoagulable blood suggests envenoming by vipers or *Rhabdophis*

Note: If the vessel used for the test is not made of ordinary glass, or if it has been cleaned with detergent, its wall may not stimulate clotting of the blood sample (surface activation of factor XI – Hageman factor) and the test will be invalid. If there is any doubt, repeat the test in duplicate, including a "control" (blood from a healthy person such as a relative)

Laboratory Studies for Asian Snake

Envenoming

Bedside Studies

Whole-blood clotting test (20WBCT)

Urine dip-stick for proteinuria, hematuria, hemoglobinuria, and myoglobinuria (may require microscopy for confirmation)

Forced expiratory peak flow

Arterial oxygen saturation assessed non-invasively using a pulse (finger) oximeter in patients with respiratory failure or shock.

Priority Laboratory Studies

Type and cross match blood for cases with severe hypotension, major ecchymosis, or swelling, or active major bleeding

(continued)

Hematocrit and hemoglobin

Prothrombin time and activated partial thromboplastin time

Platelet count

Additional Studies

Complete blood count with differential

Peripheral blood smear

Fibrinogen and fibrin degradation products

Liver function test

Serum electrolytes, blood urea nitrogen, and creatinine

Creatine phosphokinase and other enzymes

Urine examination

Electrocardiogram

Caution: Arterial puncture is contraindicated in patients with haemostatic abnormalities (Viperidae).

Plasma/serum: May be pinkish or brownish if there is gross hemoglobinemia or myoglobinemia.

Hemoglobin concentration/hematocrit: More often, there is a decrease reflecting blood loss or, in the case of Indian, Thai and Sri Lankan Russell's viper bite, intravascular hemolysis. There may be a transient increase due to hemoconcentration resulting from a generalized increase in capillary permeability (e.g., in Russell's viper bite).

Platelet count: May be decreased in envenoming, particularly by vipers.

White blood cell count: An early neutrophil leucocytosis is suggestive of systemic envenoming from any species.

Blood film: Microangiopathic hemolysis may cause fragmented red cells ("helmet cell," schistocytes).

Biochemical abnormalities: Severe local or generalized muscle damage (due to sea snake, some krait, and Sri Lankan and South Indian Russell's viper bites) will cause elevation of muscle enzymes (creatine kinase, aldolase, etc.).

Bilirubin will be elevated if there is massive extravasation of blood. Renal failure following Russell's viper, hump-nosed viper and sea snake-bites will cause a rise in potassium, creatinine, urea or blood urea nitrogen levels. Early

hyperkalemia may be a problem following extensive rhabdomyolysis in sea snake bites, particularly if there is secondary renal failure. Bicarbonate will be low in metabolic acidosis (e.g., renal failure). Hyponatremia is reported in victims of krait bites in northern Vietnam (*Bungarus candidus* and *B. multicinctus*). Arterial blood gases and pH may show evidence of respiratory failure (neurotoxic envenoming) and acidemia (respiratory or metabolic acidosis).

Urine examination: The color of the urine (pink, red, brown, black) should be noted and the urine should be tested by dipsticks for blood or hemoglobin or myoglobin. Standard dipsticks do not distinguish blood, hemoglobin and myoglobin. Hemoglobin and myoglobin can be separated by immunoassays but there is no easy or reliable test. Microscopy will confirm whether there are erythrocytes in the urine. Red cell casts indicate glomerular bleeding. Massive proteinuria is an early sign of the generalized increase in capillary permeability in Russell's viper envenoming and an early indicator of acute kidney injury.

Differential Diagnosis

Wounds from local flora, such as stinging nettles and puncture wounds from thorns may suggest snakebite, especially when the injury occurred at night. Bites and stings from local arthropods (e.g., Hymenoptera) and arachnids may cause local pain, swelling, and inflammation that may mimic the early stages of snake envenoming. The venomous bite of Asian centipedes (*Scolopendra* spp.) may cause severe pain and local inflammation, which may mimic that seen in the early hours of viper bites. However, the horizontally orientated chelicerae of *Scolopendra* spp. leave a distinctive chevron-shaped puncture wound. Scorpion stings and bites by Asian widow spiders (*Latrodectus* spp.) may be confused with neurotoxic envenoming by elapids; however, both of these arachnids cause local pain and muscular cramping with minimal local skin changes. Envenoming by *Latrodectus* spp. also is

associated with leukocytosis, moderate hypertension, and cramping of muscle groups, but true flaccid paralysis is most unlikely. In central and southern India, stings by the red Indian scorpion (*Hottentotta tamulus*) have been mistaken for bites by juvenile *Naja*. Important distinguishing features are that scorpion stings cause local piloerection, autonomic disturbances, and minimal local reaction, other than intense pain. Rarely, bites by Asian running spiders (*Lycosa* spp.), sac spiders (*Chiracanthium* spp.), or jumping spiders (*Phidippus* spp.) may suggest envenoming by Asian snakes. Tick paralysis is unique in presentation, appearing as symmetric, ascending, and flaccid paralysis, and is unlikely to be confused with snake venom paralysis. Nonvenomous snakebites and bites by moderately venomous NFFC snakes must be ruled out. NFFC snakes belonging to *Boiga* are pugnacious and capable of mild-to-moderate envenoming. Bite marks from these species have enlarged puncture wounds caused by the posterior maxillary teeth. Several arboreal green tree pythons (Pythonidae), which superficially resemble green *Trimeresurus*, possess elongated teeth suited for grasping birds; bites from these species may occasionally resemble the fang marks of vipers, but more commonly will leave numerous teeth marks, inconsistent with a viper bite. In the case of Krait bites during the night the patient may not be able to recollect the event. Absence of an apparent bite mark or failure to identify the bite mark may present a clinical scenario of acute flaccid paralysis mimicking Guillain Barre Syndrome (GBS). In GBS the paralysis is usually ascending and in Krait bite it is usually descending and more rapid in clinical course.

Emergency and Intensive Care

The care of a patient envenomed by an Asian elapid or viper should be viewed as a prolonged medical emergency, the intensive care management of which may last for days. A few patients are critically envenomed and present with

immediate life-threatening problems. Critical envenoming may result from IV injection of venom, envenoming by highly dangerous species, or prolonged delay in reaching medical care. After initial assessment and stabilization, severely envenomed patients need to be admitted to the ICU for continued antivenom administration, close medical and laboratory monitoring, and skilled nursing care.

Indications for ICU Admission in Asian Snake Envenoming

Any patient bitten by an elapid within 24 h who is showing symptoms of rapidly advancing paralysis (beyond ptosis and fasciculations)
 Blood loss (hemoglobin <8 mg/dL) and negative whole-blood clotting test or positive halo test
 Heart rate >120 beats/min and diastolic blood pressure <40 mmHg after fluid resuscitation
 Swelling and intracompartment pressures >35 mmHg
 Seizure, syncope, or pulseless episode
 Flaccid paralysis unresponsive to anticholinesterase treatment
 Respiratory rate >24/min with use of accessory breathing muscles
 Peak expiratory flow rate <80 L/min (adult)
 PaCO₂ > 45 mmHg and pH <7.35
 Creatine phosphokinase >10,000 U/L or serum potassium >6.5 mEq/L
 Cortisol <15 µg/dL and hypotension, hyperkalemia, or abdominal pain

In many parts of Asia, snakebite patients are managed in general medical wards along with many other incoming medical conditions. Often there is a huge caseload in the admitting ward. This may sometimes compromise the standard of emergency lifesaving care and worsen the outcome. Snakebite is an eminently treatable condition. A few hours vigilant care may completely reverse the outcome. One way to ensure this is to

establish a snakebite clinic/unit in the hospital where all the snakebite victims will be managed. This will help to create a set of health care personnel specifically trained and experienced in managing this condition. This will also help the best use of available logistics that is often in short supply. This approach has proven very rewarding in Chittagong Medical College Hospital in Bangladesh.

If the arrival of a patient is notified beforehand, personnel are assigned specific roles in patient care, coordination of laboratory tests, replenishment of IV supplies, transport and rewarming of the antivenom, and notification of the ICU. In the case of exotic bites, local antivenom repositories need to be located, institutional officers (e.g., zoo officials) contacted, and antivenom delivered to the hospital. Attempts should be made to locate an authority with experience treating envenoming by the same or a similar species. In North America and Europe, such personnel may include foreign medical graduates, who often have experience treating snakebite in their home country. Familiarity with the treatment of envenoming from one species does not translate to experience treating bites from other members of the genus or family. There is variability in the clinical syndromes resulting from envenoming by different species of Asian cobras and among Russell's vipers from different regions.

ICU Management of Asian Snake Envenoming For All Patients

Airway and ventilation support as needed
Continuous patient monitoring (cardiac, blood pressure, oximetry)
Serial neurologic examination
Monitor urinary output; place catheter if necessary (beware coagulopathy)
Repeat laboratory tests within 3 h of antivenom treatment
Repeat antivenom if coagulopathy, neurotoxicity, or local symptoms reappear
Monitor bitten extremity for thrombosis, compartment syndrome, or infection

Debridement of necrotic tissue
Early rehabilitation of damaged extremities

For Paralyzed Patients

Consider tracheostomy for krait-paralyzed cases
Atropine-neostigmine if appropriate
Sedation and analgesia
Early enteral nutrition

For Viper and NFFC Envenoming

Avoid giving blood products if coagulopathy is ongoing; treat with antivenom instead
Monitor alveolar-arterial gradient
Avoid arterial and central line placement, unless peripheral venous access is inadequate
Nephrology consultation for acute renal failure
Monitor for endocrinopathies (adrenal or pituitary insufficiency)

On arrival, patients require primary assessment to confirm a patent airway, spontaneous respirations, and adequate oxygenation and that they are not in shock. Patients with deteriorating respiratory status should be promptly intubated with a laryngeal mask airway or endotracheal tube (Figs. 37 and 39). Nasotracheal tubes should not be used for envenoming by vipers and, probably, *Rhabdophis* spp. owing to risk of bleeding and formation of compressive blood collections in the sinuses. Patients with respiratory paralysis do not require paralytics because the muscles of the upper airway are usually lax. Because patients are alert during paralysis, however, the use of benzodiazepines or other amnestic agents or haloperidol is compassionate and clinically indicated if not otherwise contraindicated by hypotension. Ketamine (1–2 mg/kg IV given over 2 min) may be used in hypotensive patients because it does not lower the blood pressure. In normotensive patients with coagulopathy, ketamine should be used with caution because it increases intracranial pressure and potentially

could increase the likelihood of an intracranial bleed.

Severely envenomed patients require fluid resuscitation. The placement of IV lines also permits blood to be drawn for the bedside evaluation of coagulation and for stat blood samples to be sent to the laboratory. At least two IV lines are needed to allow the separate delivery of antivenom, ionotropes, and IV fluids. IV lines should not be placed in the envenomed extremity, and in patients who are coagulopathic, avoid the subclavian, femoral, and jugular veins, if at all possible. Adult patients are hydrated with boluses of crystalloid as indicated by ongoing assessment of hemodynamic status. Central venous catheterization should not be attempted, unless it is found to be absolutely necessary and significant coagulopathy has been excluded. Fluid volume overload should be avoided, particularly in elderly patients and small children, because antivenom administration also requires IV fluids. In cases of envenoming with coagulopathy, saphenous vein cut-down and ligature and, in children, interosseous access are alternative hydration sites in an extreme situation. Arterial access sites not only are unnecessary but also may prove disastrous in a patient with coagulopathy. Ionotropic agents are seldom required and should be used only when 3–4 L of IV hydration has failed to relieve hypotension. Volume status may be monitored by measuring urine output.

Envenoming by Asian vipers often results in shock secondary to hemorrhagin-induced extravasation of fluid. Packed red blood cells and albumin help to offset fluid extravasation by increasing oncotic pressure. In many parts of Asia, the risk of blood-borne pathogens, such as malaria, filariasis, and viral diseases, may still exist, however, and pathogen testing of blood supplies may be either dubious or nonexistent. Reliance on synthetic colloid replaces these risks with other concerns. The IV administration of 6% hetastarch may interfere with factor VIII activity and may increase the activated partial thromboplastin time. Dextran 40 also should be avoided because it inhibits platelet aggregation, induces

fibrinolysis, and activates factor VIII [124]. In many parts of Asia, 10% pentastarch, which does not interfere with coagulation, is often available and should be considered. Many physicians favor administration of hypertonic saline; however, evidence that it is comparable to colloid fluids is lacking [125].

Criteria for ICU Discharge in Asian Snake Envenoming

Reversal of coagulopathy for >12 h

Resolution of neuromuscular symptoms for >24 h

50% improvement in creatine phosphokinase, hyperkalemia, and fibrinogen titer

Peak expiratory flow rate >100 L/min, adequate oximetry, or arterial blood gas on room air

Stable or improving urine output

Many patients are treated in the field with tourniquets, lymphatic bands, and pressure immobilization dressings. These techniques serve to compartmentalize venom and by-products of ischemia. The physician who receives patients treated with these methods (see earlier section on first aid) should remove these bands only *after* IV access is obtained, the patient is hydrated, and, ideally, antivenom therapy is started (if indicated). In the cobra bite cases, slow removal of the first aid still resulted in dramatic symptoms despite prehydration and treatment with three or more vials of appropriate antivenom (see Table 9). Significant bleeding may occur from incisions made to the fang marks, and occasionally arterial bleeding is seen. Medical care should make use of direct and indirect pressure with a sterile dressing and elevation. Wound inspection and cleaning is performed after lifesaving interventions are completed. An experienced surgeon should be consulted for convincing evidence of compartment syndrome or to identify other threats to tissue or limb. Principles of emergency care for Asian snake envenoming are summarized in Table 8.

Table 8 Emergency care of severe envenoming by Asian snakes

Assign tasks according to medical skill of personnel
In the emergency department or ICU, personnel are assigned to call the laboratory; collect IV supplies; locate, transport, rewarm, and reconstitute antivenom; and identify local snakebite experts
Airway/ventilation
Preoxygenate any patient with respiratory distress, intubate endotracheally, and provide mechanical ventilatory support. Neuromuscular blocking agents are often not necessary for venom-paralyzed patients; however, use of sedatives is appropriate, provided that caution is exercised to prevent hypotension
Fluid volume resuscitation
Place two large-gauge IV lines in the nonenvenomed extremity, and draw blood for laboratory studies and bedside clotting tests. Hydrate adult patients with 300–500 mL fluid boluses every 5 min (children 20 mL/kg) until perfusion is restored. Use of inotropes (dopamine 10–20 µg/kg/min) should be reserved for cases that fail to respond to 3–4 L hydration (packed red blood cells or other colloid should be used in hypotensive-hypovolemic patients with severe swelling). Location of cryptic bleeding should be identified by imaging studies (e.g., CT or ultrasound)
Local care
Fang marks should be inspected, retained fangs removed, and skin irrigated to remove unabsorbed venom. The bite site should not be otherwise manipulated
Patients with tourniquets or pressure dressings should be hydrated and pretreated with antivenom. The extremity should be kept immobilized in a functional position at or below heart level
Antivenom treatment
Prepare standby epinephrine (0.5 mL 1/10,000 in syringe taped to the IV bag, or alternatively mix 1 mg epinephrine in 250 mL D5W (4 mg/mL) and hang/place on IV pole or at bedside). For noncritical patients, start antivenom at low infusion rates, and adjust rate upward as tolerated by patient's symptoms
Question the patient about changes in symptoms, and reassess vital signs for 5–10 min before continuing antivenom. Stop antivenom if hypersensitivity reaction (anaphylactic reaction) develops, treat with IM or IV epinephrine (use IV route only with great caution), and resume antivenom at a slower rate
Acetylcholinesterase inhibitors
Acetylcholinesterase inhibitors should be considered in any patient with neurotoxic symptoms. Patients are first pretreated with atropine (0.6–1 mg for adult and 50 µg/kg children) and tested for edrophonium hypersensitivity. Short-acting edrophonium chloride (Tensilon) is ideal for this test but is rarely available in the region. It is given by slow intravenous injection in an adult dose of 10 mg, or

(continued)

Table 8 (continued)

0.25 mg/kg for children. Patients who respond convincingly can be maintained on neostigmine methylsulfate, 0.5–2.5 mg every 1–3 h up to 10 mg/24 h maximum for adults or 0.01–0.04 mg/kg every 2–4 h for children by intramuscular, intravenous or subcutaneous injection together with atropine to block muscarinic side effects [116]

Nasogastric tubes

Nasogastric tubes may be placed to reduce regurgitation/aspiration and in cases of extended paralysis to assist in hydration and nutrition, but are best avoided, if possible, in patients with active coagulopathy

CT computed tomography, D5W 5% dextrose in water, ICU intensive care unit, IV intravenous

Immunotherapy

Antivenom is the concentrated enzyme-refined gamma immunoglobulin (or immunoglobulin fragments) of horses or sheep which have been immunized with venom. The only definitive treatment for snake envenoming is antivenom. Antivenom does more than save lives; it also conserves blood products and reduces the attendant risk of blood-borne infection; interrupts progression of paralysis, hence conserving mechanical ventilators (or personnel needed to manually ventilate patients); and shortens hospital stay. Antivenom also reduces local injury, lessening permanent disabling sequelae. It is likely that antivenom speeds convalescence, potentially allowing wage earners to return to work faster and with fewer complications (although there is no controlled trial evidence to support this). In developing regions and in resource-rich countries, antivenom treatment is cost-effective, compassionate, and usually the most important contribution made by the health care provider.

The first decision regarding antivenom treatment is whether the patient requires antivenom at all. Many bites are dry or result in trivial envenoming. The cases most likely to challenge the physician involve bites from kraits, coral snakes, and Philippine cobras that have not yet produced neurotoxic symptoms. Envenomings from these species are also the

cases that show maximal benefit when antivenom is given early.

Antivenom should be given to any patient with symptomatic bites to the fingers or toes, severe local symptoms, rapidly progressing symptoms, or any evidence of systemic envenoming. Evidence of systemic envenoming includes coagulopathy (positive 20WBCT or prolonged prothrombin time and partial thromboplastin time; bleeding from the gums, gastrointestinal tract, or genitourinary tract); syncope; seizure; cardiac arrhythmias; perioral paresthesias; developing neurotoxic paralysis (even just ptosis), or any unusual neurologic symptom that cannot be attributed to another cause.

Indications for Antivenom

Antivenom treatment is recommended if and when a patient with proven or suspected snake-bite develops one or more of the following signs [116]:

Systemic Envenoming

1. Hemostatic abnormalities: Spontaneous systemic bleeding (clinical), coagulopathy (20WBCT or other laboratory tests such as prothrombin time), or thrombocytopenia ($<100 \times 10^9/l$ or $100\ 000/cu\ mm$) (laboratory).
2. Neurotoxic signs: ptosis, external ophthalmoplegia, paralysis, etc. (clinical).
3. Cardiovascular abnormalities: hypotension, shock, cardiac arrhythmia (clinical), abnormal ECG.
4. Acute kidney injury (renal failure): oliguria/anuria (clinical), rising blood creatinine/urea (laboratory).
5. Hemoglobinuria/myoglobinuria: dark brown urine (clinical), urine dipsticks, other evidence of intravascular hemolysis or generalized rhabdomyolysis (muscle aches and pains, hyperkalemia) (clinical, laboratory).

Supporting laboratory evidence of systemic envenoming (see above).

Local Envenoming

1. Local swelling involving more than half of the bitten limb (in the absence of a tourniquet) within 48 h of the bite. Swelling after bites on the digits (toes and especially fingers).
2. Rapid extension of swelling (for example, beyond the wrist or ankle within a few hours of bite on the hands or feet).
3. Development of an enlarged tender lymph node draining the bitten limb.

Throughout Asia, antivenom is expensive relative to the cost of other medical services. High cost, limited shelf life, and injudicious use result in frequent shortages, particularly among the rural hospitals. Appropriate species-specific antivenom is often unavailable. Ideally, nonexpired, lyophilized, monospecific antivenoms provide the best results, require the lowest dosages, and have the fewest side effects. Antivenom that has exceeded the expiration date maintains neutralizing activity, even when stored at room temperature, and should be used if no alternative is available. “Specific” antivenom means that the antivenom has been raised against the venom of the snake that has bitten the patient and that it can therefore be expected to contain specific antibody that will neutralize that particular venom and perhaps the venoms of closely related species (paraspecific neutralization). Monovalent (monospecific) antivenom neutralizes the venom of only one species of snake. Polyvalent (polyspecific) antivenom neutralizes the venoms of several different species of snakes, usually the most important species, from a medical point of view, in a particular geographical area [116]. In many parts of Asia, bivalent and polyvalent antivenoms are widely available. These antivenoms have neutralizing activity distributed across the different venoms used in the immunization process, and larger doses often are required compared with monovalent antivenoms. Bivalent and polyvalent antivenoms should be used when the identity of the snake is unknown or when monovalent antivenom is not available. When given a choice, the physician should select an antivenom prepared using venom from the same species and ideally

from the same region. When the culprit snake is unknown, the physician should select antivenom based on the constellation of local findings, the presence of systemic symptoms, the results of clotting tests, the circumstances of the bite, and the epidemiology of bites involving local venomous species. For a reference to currently available antivenom in a specific region in Asia, readers are advised to consult WHO antivenom site (<http://apps.who.int/bloodproducts/snakeantivenoms/database/>) or the Clinical Toxinology Resources Website (www.toxinology.com).

Antivenom treatment should be given as soon as it is indicated, even when systemic envenoming has persisted for several days. In case of persistent hemostatic abnormalities, it is appropriate to give antivenom for as long as evidence of the coagulopathy persists, even for two or more weeks [116] postbite. The role of antivenom in prevention of local necrosis remains controversial, but there is some clinical evidence that, to be effective in this situation, it must be administered within the first few hours after the bite [126].

Contraindications to Antivenom

There is no absolute contraindication to antivenom treatment. But patients who have a past history of reaction to horse (equine) or sheep (ovine) serum (for example, after treatment with equine anti-tetanus serum, equine antirabies serum, or equine or ovine antivenom) and those with a strong history of atopic diseases (especially severe asthma) are at increased risk of severe reactions and should therefore be given antivenom only if they have signs of systemic envenoming. In such cases, it is reasonable to consider prophylactic subcutaneous epinephrine prior to commencing antivenom.

Selection, Storage, and Shelf Life of Antivenom

Antivenom should be selected based on the specificity (paraspecificity) to the known or suspected biting snake. If a liquid antivenom becomes opaque, it should not be used. Lyophilized antivenoms (shelf life about 5 years) should be stored at below 25 °C

and liquid antivenoms (shelf life 2–3 years) should be stored at 2–8 °C and should not be frozen. If properly stored, antivenom can be expected to retain useful activity for months or even years after the stated expiry date [127]. When there is no alternative, recently expired antivenoms may be used in patients with severe envenoming.

Monovalent (monospecific) antivenom should be used when available and more importantly when the biting species is definitely known. It may be less expensive and a lower dose of antivenom may be required than with a polyvalent (polyspecific) antivenom. However, polyvalent antivenom may be more potent than a monovalent antivenom as immunization of an animal with venoms of several related species of snakes (e.g., Viperidae) may produce an enhanced antibody response to common antigens. In many parts of Asia, immuno-diagnosis of species is not possible and the offending snake often cannot be identified. In this situation, polyvalent (polyspecific) antivenoms are preferred and they can be equally effective as monovalent (monospecific) ones.

Administration of Antivenom

Antivenom should be given by the intravenous route whenever possible. Freeze-dried (lyophilized) antivenoms are reconstituted, usually with 10 ml of sterile water for injection per ampoule.

Epinephrine (adrenaline) should always be ready, drawn up before antivenom is administered.

Recommended Methods of Administration

1. Intravenous “push” injection: Reconstituted freeze-dried antivenom or neat liquid antivenom is given by slow intravenous injection (not more than 2 ml/min).
2. Intravenous infusion: Reconstituted freeze-dried or neat liquid antivenom is diluted in approximately 5–10 ml of isotonic fluid per kg body weight (i.e., 250–500 ml of isotonic saline or 5% dextrose in the case of an adult patient) and is infused at a constant rate over a period of about one hour.

Patients must be closely observed for at least one hour after starting intravenous antivenom

administration, so that early anaphylactic antivenom reactions can be detected and treated early with epinephrine (adrenaline). IV push method has the advantage that the health care personnel administering the antivenom can detect some early reactions immediately.

Local administration of antivenom at the site of the bite: It is extremely painful, may increase intracompartmental pressure, is not recommended, and should not be used.

Intramuscular injection of antivenom: Bioavailability of antivenoms are poor after IM injection (specially gluteal region) as these are large molecules ($F(ab')_2$ fragments or sometimes whole IgG) which are absorbed slowly via lymphatics. They fail to reach the desired blood levels. There is additional risk of hematoma formation in patients with hemostatic abnormalities and not to forget the pain of injection of large volumes of antivenom.

The only situations in which intramuscular administration might be considered [116]:

1. Absence of anyone capable of giving an intravenous injection
2. At a peripheral first aid station, before a patient with obvious envenoming is put in an ambulance for a journey to hospital that may last several hours
3. On an expedition exploring a remote area very far from medical care
4. When intravenous access has proved impossible

Antivenom must never be given by the intramuscular route if it can be given intravenously.

Epinephrine (adrenaline) should be kept readily available although the risk of antivenom reactions is less with intramuscular (than intravenous) administration.

If IM route is inevitable, the total dose of antivenom should be given in the upper anterolateral region of both thighs divided in a number of sites. At each site no more than 5–10 ml should be given deep intramuscularly and the site should be massaged afterwards to

aid absorption. It is particularly difficult in children as they have small muscle mass.

Dose of Antivenom

Manufacturers' recommendations may not represent the dose required to cure a human patient as these are usually based on in vitro assays. These recommendations are made based on the average venom yield of captive snakes during milking and amount of antivenom needed to neutralize that volume. In practice, the choice of an initial dose of antivenom is usually empirical. The neutralizing power of antivenoms varies from batch to batch, and any recommendation may become invalid when the manufacturers change the strength of their antivenom. Suggested initial doses of some of the available antivenoms are given in Table 9.

Children Must Be Given Exactly the Same Dose of Antivenom as Adults

For choice of antivenom, see also WHO venomous snakes and antivenoms website <http://apps.who.int/bloodproducts/snakeantivenoms/database/>.

Follow-up After Antivenom

After a dose of appropriate antivenom, the following responses should be observed:

- (a) Nausea, headache, and generalized aches and pains usually disappear quickly. The patient should feel better. But this may also be partly due to a placebo effect.
- (b) Spontaneous systemic bleeding (e.g., from gums) usually stops within 15–30 min.
- (c) Blood coagulability (as measured by 20WBCT) is usually restored in 3–9 h. Bleeding from wounds usually stops sooner.
- (d) Blood pressure may increase within the first 30–60 min in shocked patients and arrhythmias such as sinus bradycardia may resolve.
- (e) Neuroparalysis of the postsynaptic type (cobra bites) may begin to improve as early as 30 min after antivenom, but may take several hours. Envenoming with presynaptic

toxins (kraits and sea snakes) will not respond in this way.

- (f) Active hemolysis and rhabdomyolysis may cease within a few hours, and the urine returns to its normal color.

Treating physicians should be vigilant even after an initial response to antivenom has been observed. Due to continuing absorption of venom from the “depot” at the site of the bite, and elimination of antivenom from the body [128, 129] and redistribution of venom from the tissues into the vascular

space, as the result of antivenom treatment [130], signs of systemic envenoming may recur within 24–48 h. This phenomenon has been described as **Recurrence of systemic envenoming**. This is more important in patients with coagulopathy (envenomed by vipers), though neurotoxic envenoming after cobra bite has also been implicated.

Criteria for Repeating Antivenom

1. Persistence of blood incoagulability (as measured by 20WBCT) after 6 h or recurrence of

- bleeding after 1–2 h and if patients continue to bleed briskly [116].
2. Deteriorating neurotoxic or cardiovascular signs after 1–2 h.
 3. The initial dose of antivenom should be repeated, and patient should be reevaluated for need of full supportive treatment.

Supportive/Ancillary Treatment

Antivenom needs time to act. It is expected to neutralize the circulating venom and thus prevent progression of envenoming, but already established toxicity needs to be addressed simultaneously [116]. The patient may require support of cardiovascular, respiratory, or renal function until the damaged organs and tissues recover.

There may be a situation in many parts of Asia, when antivenom is not available or specific antivenom is not available. The following conservative measures are suggested:

In case of neurotoxic envenoming with respiratory paralysis, assisted ventilation with room air or oxygen has proved effective and should be provided. Many times it has been rewarded with complete recovery, even after being maintained for more than a month. When no mechanical ventilation is available manual ventilation (anesthetic bag) by doctors, medical students, relatives, and nurses has been effective.

Anticholinesterases should always be tried. Anticholinesterase drugs have a potentially very useful, though variable, effect on neurotoxicity especially in patients bitten by cobras [85, 86, 131].

A trial of anticholinesterase (e.g., “Tensilon test”) should be performed in every patient with neurotoxic envenoming. However, this should not delay endotracheal intubation or treatment with antivenom. Patients must be observed closely while the trial of anticholinesterase is being carried out as they may deteriorate. Baseline measurements are noted against which the effectiveness of the anticholinesterase will be assessed.

First atropine sulfate (0.6 mg for adults; 50 µg/kg for children) or glycopyrronium is given by

intravenous injection followed by neostigmine bromide or methylsulfate (Prostigmin) (or distigmine, pyridostigmine, ambenonium, etc. in appropriate doses) by intramuscular injection 0.02 mg/kg for adults, 0.04 mg/kg for children. Short-acting edrophonium chloride (Tensilon) which is ideal for this test is rarely available in many parts of Asia (slow intravenous injection in an adult dose of 10 mg, or 0.25 mg/kg for children).

The patient is observed over the next 30–60 min (neostigmine) or 10–20 min (edrophonium) for signs of improved neuromuscular transmission. Ptosis may disappear and ventilatory capacity (peak flow, FEV-1 or maximum expiratory pressure) may improve.

Patients who respond convincingly to this can be maintained on intramuscular, intravenous, or subcutaneous injection of neostigmine methylsulfate, 0.5–2.5 mg every 1–3 h up to 10 mg/24 h maximum for adults or 0.01–0.04 mg/kg every 2–4 h for children together with atropine to block muscarinic side effects. Patients who are able to swallow tablets may be maintained on atropine 0.6 mg twice each day, neostigmine 15 mg four times each day, or pyridostigmine 60 mg four times each day.

In case of coagulopathy, strict bed rest and avoidance of even minor trauma should be observed. Transfusion of clotting factors and platelets, ideally, fresh frozen plasma (FFP) and cryoprecipitate with platelet concentrates or, if these are not available, fresh whole blood may be considered, but as this is a consumption coagulopathy the role of these is controversial. Any decision to administer should be clinically weighted against the situation. Intramuscular injections should always be avoided.

Hypovolemia should be corrected with colloid/crystalloids (preferably controlled by observation of the central venous pressure). In patients with generalized increase in capillary permeability vasopressor drugs (dopamine) may also be tried. Atropine should be given to patients with hypotension associated with bradycardia.

Acute kidney injury:

Oliguric phase of renal failure: Most, but not all, patients with acute renal failure are oliguric, defined as a urine output of less than 400 ml/day

or less than 20 ml/h. Conservative management may avoid the need for dialysis.

If the patient has intravascular volume depletion, indicated by supine or postural hypotension, or empty neck veins, an intravenous fluid challenge should be tried.

In adults, two litres of isotonic saline can be given over one hour or until the jugular venous pressure/central venous pressure has risen to 8–10 cm above the sternal angle (with the patient propped up at 45°). The patient should be closely observed for pulmonary edema, in which case infusion must be stopped immediately. A urethral catheter should be inserted with full sterile precautions. If the urine output does not improve, a furosemide and/or mannitol challenge may be tried, but these are not of proven benefit. In some patients it can be difficult to determine the height of the central venous pressure by clinical examination. Direct measurement of central venous (superior vena caval) pressure through a long catheter, preferably inserted at the antecubital fossa can be helpful in this circumstance. 100 mg of furosemide is injected slowly (4–5 mg/min). If this does not induce a urine output of 40 ml/h, give a second dose of furosemide of 200 mg.

No further diuretics should be given if the urine output does not improve despite these challenges. Fluid intake should be restricted to a total of the previous day's output plus "insensible losses" (500–1000 ml/day). If possible, the patient should be referred to a renal unit. Infections should be prevented or treated promptly with non-nephrotoxic antibiotics (i.e., avoid aminoglycosides). Serum potassium, urea, creatinine and, if possible, pH, bicarbonate, calcium, and phosphate should be monitored frequently. If this is not possible, the electrocardiogram (ECG) should be examined for evidence of hyperkalemia, especially following bites by sea snakes, or Sri Lankan or South Indian Russell's vipers, or if rhabdomyolysis or intravascular hemolysis is suspected (dark brown urine).

If there are tall peaked T waves, prolonged P-R interval, absent P waves, wide QRS complexes on ECG or potassium >6.0 mmol/l, give 10 ml of 10% calcium gluconate intravenously over 2 min

(with ECG monitoring if possible); this may be repeated up to three times. Give 50 ml of 50% dextrose with 10 units of soluble insulin intravenously, Sodium bicarbonate (40 ml of 8.4%) by slow intravenous infusion and a β_2 agonist aerosol by inhaler or nebulization (e.g., salbutamol 5–10 mg) may also be used. Sodium bicarbonate should also be given if the patient is hypotensive or there is signs of acidosis (deep sighing "Kussmaul" respirations, very low plasma bicarbonate concentration or very low pH – <7.10). After calculating the bicarbonate deficit it may be repeated, but it carries the risk of fluid overload in patients with no or little output and the risk of profound hypocalcemia and fits, especially in patients with rhabdomyolysis.

If there is no clinical improvement dialysis is required.

In the case of myoglobinuria or hemoglobinuria presenting with dark brown urine, correct hypovolemia with intravenous fluid. Acidosis can be corrected with a slow intravenous infusion of 50–100 mmol of sodium bicarbonate and consider a single infusion of 200 ml of 20% mannitol intravenously over 20 min. This must not be repeated as there is a chance of fluid and electrolyte imbalance.

Local necrosis, intracompartmental syndromes, and thrombosis of major vessels are more likely in patients who cannot be treated with antivenom. The risks of surgical intervention in a patient with consumption coagulopathy must be balanced against the complications of local envenoming. Prophylactic broad spectrum antimicrobial treatment should be given (see below).

Antivenom Reactions

Administration of antivenom is associated with inherent risk of reactions. Except in rare cases of presensitization (IgE-mediated Type I hypersensitivity) by previous exposure to animal serum, for example, to equine antivenom, tetanus-immune globulin, or rabies-immune globulin, the risk of reaction is mostly dose related. There are three types of reactions:

1. Early anaphylactic reactions: These usually occurs within 10–180 min of starting antivenom. It starts with an itch often over the scalp and then the patient develops urticaria, restlessness, dry cough, nausea, vomiting, fever, abdominal colic, diarrhea, and tachycardia. Physicians should be vigilant at this stage, as some of these patients may develop severe life-threatening anaphylaxis: hypotension, bronchospasm, and angioedema. In most cases, these reactions are not IgE-mediated type I hypersensitivity reactions to horse or sheep proteins as there is no evidence of specific IgE, either by skin testing or radioallergosorbent tests (RAST). The proposed likely mechanisms for these reactions are direct stimulation of mast cells or basophils by antivenom protein or complement activation by IgG aggregates or residual Fc fragments.
2. Pyrogenic (endotoxin) reactions: They are commonly reported and usually develop 1–2 h after starting infusion of antivenom. Patients usually develop chills (rigors), fever, vasodilatation, and a fall in blood pressure. Children may develop febrile convulsions. These reactions are due to the presence of pyrogenic impurities during the manufacturing process.
3. Late (serum sickness type) reactions: After 1–12 (mean 7) days of treatment with antivenom some of the patients may develop late reactions characterized by fever, nausea, vomiting, diarrhea, itching, recurrent urticaria, arthralgia, myalgia, lymphadenopathy, periarticular swellings, mononeuritis multiplex, proteinuria with immune complex nephritis, and, rarely, encephalopathy. Patients who suffer early reactions and are treated with antihistamines and corticosteroid are less likely to develop late reactions.

Prevention of Antivenom Reactions

Adrenaline (epinephrine) is the most effective treatment for anaphylactic reactions, by reducing bronchospasm and capillary permeability. However, the risks of adrenaline make it less attractive for prophylaxis, especially in children, pregnant women, and in patients with heart disease. In a large double-blind, placebo-controlled study

carried out in Sri Lanka, 1007 patients were randomized: adrenaline (0.25 ml of a 0.1% solution subcutaneously), promethazine (25 mg intravenously), and hydrocortisone (200 mg intravenously), each alone and in combinations. Adrenaline significantly reduced severe reactions to antivenom (compared with placebo) by 43% (95% CI 25–67) at 1 h and by 38% (95% CI 26–49) up to and including 48 h after antivenom administration. Adding hydrocortisone negated the benefit of adrenaline [132].

Treatment of Antivenom Reactions

Early anaphylactic and pyrogenic antivenom reactions: Severe, life-threatening anaphylaxis can evolve rapidly. At the very first sign of a reaction, even when only a few spots of urticaria have appeared or at the start of itching, tachycardia, or restlessness, epinephrine (adrenaline) should be given intramuscularly (into upper lateral thigh) in an initial dose of 0.5 mg for adults and 0.01 mg/kg body weight for children. If the patient's condition is deteriorating, dose can be repeated every 5–10 min.

Additional treatment: Antihistamine anti-H1 blocker such as chlorphenamine maleate (adults 10 mg, children 0.2 mg/kg by intravenous injection over a few minutes) should be given followed by intravenous hydrocortisone (adults 100 mg, children 2 mg/kg body weight) after epinephrine (adrenaline).

In pyrogenic reactions: Antipyretics (paracetamol by mouth or suppository). Intravenous fluids should be given to correct hypovolemia.

Treatment of late (serum sickness) reactions:

Oral antihistamine for 5 days. If no improvement after 24–48 hrs a 5-day course of prednisolone should be given.

Doses: Chlorphenamine: adults 2 mg six hourly, children 0.25 mg/kg/day in divided doses.

Prednisolone: adults 5 mg six hourly, children 0.7 mg/kg/day in divided doses for 5–7 days.

Treatment of the Bitten Part

Once the acute management of the patient is over, the treating physician should take care of the

bitten part. The bitten part which is most of the time a limb, may be painful, swollen, tender. It should be kept in the most comfortable position. There may be multiple large, tense bulae. They should be aspirated only if they seem likely to rupture. The limb should not be excessively elevated as this may reduce arterial perfusion pressure in a tensely swollen limb and increase the risk of intracompartmental ischemia. The bite site should be carefully inspected over the next few days as there may be necrosis of local tissue which may warrant surgical attention. There may also be infection due to organisms present in the snake's oral cavity and also secondary bacterial infection. Immediate broad spectrum antibiotics (e.g., amoxicillin or a cephalosporin plus a single dose of gentamicin plus metronidazole) and tetanus prophylaxis are recommended.

Compartmental Syndrome

Direct muscle injury leading to muscle swelling may result in increased pressure especially when tight fascial compartments like the digital pulp space or anterior tibial compartments are involved. An immobile, tensely-swollen, cold and apparently pulseless snake-bitten limb may suggest the possibility of increased intracompartmental pressure. Intracompartmental pressures exceeding 40 mmHg (less in children) may carry a risk of ischemic necrosis (e.g., Volkmann's ischemia or anterior tibial compartment syndrome).

Clinical features of a compartmental syndrome

- Disproportionately severe pain
- Weakness of intracompartmental muscles
- Pain on passive stretching of intracompartmental muscles
- Hypoesthesia of areas of skin supplied by nerves running through the compartment
- Obvious tenseness of the compartment on palpation

The treating physician should be very "conservative (in approach)" before taking the decision for fasciotomy. Fasciotomy should not be contemplated until hemostatic abnormalities have been

completely reversed. Even fasciotomy may not save the envenomed and swollen muscles which may already be irreversibly damaged by the direct effects of the venom [11].

Early Treatment with Antivenom Remains the Best Way of Preventing Irreversible Muscle Damage

Criteria for fasciotomy in snake-bitten limbs:

- (a) Hemostatic abnormalities have been corrected (antivenom with or without clotting factors)
- (b) Clinical evidence of an intracompartmental syndrome
- (c) Intracompartmental pressure >40 mmHg (in adults)

Rehabilitation

Measures for rehabilitation should start once the acute management is over. This starts with maintaining the affected limb in a functional position. Care should be taken to prevent deformity of the ankle and stiffness of muscles. Local tissue necrosis and development of gangrene warrant surgical consultation and management. Physiotherapy may accelerate functional recovery of the bitten limb, and it may be continued at home after the patient is discharged.

Special Populations

Pediatric Patients

In tropical Asia, children are likely to be envenomed by many species. Due to their smaller size, children seem to be at increased risk of intravenous envenoming. Also, children are uniquely subject to krait envenoming as a result of sleeping on the floor in rural houses. The symptoms of snakebite in children are often accelerated, more severe, and more resistant to treatment than in adults. In rural health clinics, pediatric-size oral airways and IV supplies are often unavailable. All children with indications for antivenom should receive the same treatment doses as adults, and the antivenom should

be volume concentrated (e.g., 100–200 mL total volume) to allow for administration of the total dose. A subset of children with apparent poor prognosis after snakebite is the malnourished. Many nutritionally compromised children are bitten while gathering food. In this group, close monitoring of serum electrolytes during treatment is an absolute necessity. After treatment, malnourished patients are likely to benefit from antihelminthic therapy, micronutrient repletion, and a high protein-calorie diet, all of which may support postenvenoming healing.

Pregnant Patients

Pregnant women occasionally may be envenomed and should be treated as nonpregnant patients with a few exceptions. The stress of envenoming can cause *ante- and postpartum hemorrhage, premature labor, abortion/stillbirth, and fetal distress*. The distribution of venom, and likely of antivenom, in pregnant women depends on the molecular weight of venom antigen and antivenom immunoglobulin. Small proteins, including several postsynaptic neurotoxins, may be capable of traversing the placenta and entering the fetal circulation. The effects of neurotoxin on a fetus residing within a paralyzed-ventilated mother are unknown. In addition, there are no data regarding the ability of whole equine or ovine IgG immunoglobulins to traverse the human placenta in a manner akin to maternal IgG. Similarities in molecular weight and amino acid sequence suggest that this movement might be a possibility. Regardless, the pregnant patient and her fetus (*uterine contractions and fetal heart rate*) should be monitored closely and treated based on the mother's symptoms. Cesarean section should not be attempted unless absolutely necessary to save the mother; it should not be undertaken unless coagulopathy has not occurred or has resolved with antivenom therapy.

Elderly Patients

The elderly and patients with comorbidities also are at increased risk of severe reactions to

snakebite. Bites by vipers may severely stress the patient's cardiac reserve [133], and many patients are unable to maintain adequate cardiac output during venom-induced hypovolemic episodes. All elderly patients and patients with heart disease, diabetes, and frail state require close cardiac monitoring and monitoring of serum creatine phosphokinase and creatinine.

Common problems in treatment of Asian snakebite

Problem	Response
Misdiagnose cobra bite as viper bite	Consider cobras in the evaluation of bites with local symptoms; follow-up for neurotoxicity
Missed krait or Philippine cobra bite	These species cause minimal local symptoms and may be dismissed as dry bites. Confirm the identity of seemingly innocuous species or admit patients with suspicious history
Sudden respiratory failure	Reassess progression of paralysis and intubate patient before respiratory failure is advanced
Missed hemolysis or hemorrhage	Extravasation leads to hemoconcentration of red blood cells, which may mask red blood cell lysis. Monitor patients with swelling, check urine output, monitor for hemoglobinuria, and obtain peripheral blood smear for evidence of hemolysis
Delayed presentation to hospital	Monitor patients envenomed by kraits and <i>Naja philippinensis</i> and treat when first symptoms appear; locate antivenom, intravenous fluids, and emergency supplies in advance of patient arrival
Insufficient antivenom	Repeat patient and laboratory assessment to determine if more antivenom is likely to be needed. Plan in advance
Incorrect antivenom	Match the culprit snake with the scientific name and region listed on the antivenom package insert. Attempt to locate more appropriate antivenom (zoos, poison control center, research center)

Acknowledgments The authors would also like to acknowledge Michael V. Callahan, Charles Lee, and Richard Y Wang, who were the authors of the last edition. A

Ghose would like to acknowledge and thank Professor David A Warrell and Professor Md Abul Faiz for being a teacher, guide and mentor. The text is heavily influenced by publications and lectures of Prof D A Warrell.

Australia and New Guinea are home to the most toxic of all the world’s snakes [1]. The snake fauna is dominated by venomous species, and most snakes that measure greater than 1 m long are potentially lethal [1–4]. Snakebite is a major health issue in New Guinea, where high rates of snakebites and snakebite deaths have been reported [3]. In Australia, with an equally deadly fauna, snakebite is uncommon, however, and fatalities are uncommon to rare [1, 4, 5]. This difference reflects the urban lifestyle in Australia, the well-developed health care system, and the wide availability of intensive care units and antivenoms.

Snake Fauna

In contrast to virtually all other regions, Australia, New Guinea, and the Pacific are dominated by elapid snakes [1–3], with a smattering of non-front-fanged colubrids (NFFC) snakes [6] (► Chap. 124, “Non-Front-Fanged Colubroid Snakes”; none lethal) and no vipers.

Australia

Australia is home to seven families of snakes (Table 1), of which only three contain venomous species, and only one contains species likely to cause human fatalities [1, 2, 4, 6].

Non-front-Fanged Colubroid Snakes

There are only a few NFFC [6] species in Australia, mostly confined to northern and eastern continental Australia, and only one of these is significantly venomous, the brown tree snake, *Boiga irregularis* (Colubridae; Fig. 1) [1, 2, 4]. Even this species does not pose a threat to human life, although infants bitten by immigrant snakes on Guam may occasionally develop significant envenoming [6]. Few bites are recorded from Australia, however, none significant [6]. The NFFC “backfanged” homalopsids (Homalopsidae; notably *Cerberus australis*, *Fordonia leucobalia*, *Myron* spp., *Pseudoferania*

Table 1 Snake families in Australia and the Pacific Islands

Family	Common name	Distribution
Typhlopidae	Blind snakes	Australia, New Guinea, some Pacific islands
Boidae	Pythons and boas	Australia, New Guinea, Samoa, Fiji, Solomon islands
Acrochordidae	File snakes	Australia, New Guinea
Colubridae	Colubrid NFFC snakes [6]	Australia, New Guinea (including Bougainville), Solomon islands, Guam, Fiji
Natricidae (Note that Cogger, 2014, still lists this as a subfamily of Colubridae) [2]	Natricine NFFC snakes	Australia, New Guinea, and beyond
Homalopsidae	Homalopsid NFFC snakes	Australia, New Guinea and beyond
Elapidae (includes Hydrophiinae)	Elapid (cobra type -) snakes (includes sea snakes)	Australia, New Guinea (including Bougainville), Solomon islands, Fiji. Sea snakes found throughout Pacific adjacent to islands, plus one pelagic species

polylepis), though venomous, are not considered a risk to humans [2, 6].

Elapids

Elapids dominate the terrestrial and aquatic Australian snake fauna [1, 2]. Sea snakes of numerous species (about 36 species) abound in the waters of coastal Australia except southern waters [2]. On land, elapids account for 97 of the 126 species of terrestrial (excluding blind snakes; Typhlopidae) and freshwater snakes [2]. Although all elapids are venomous and possess fangs, only

Fig. 1 Brown tree snake, *Boiga irregularis* (Copyright © Dr. Julian White)

about 33 terrestrial species are large enough or toxic enough to pose a significant threat to humans [1, 2, 4, 5]. This latter group is divided into five distinct groups (Table 2) [1, 4].

Brown Snakes. The brown snakes, genus *Pseudonaja*, occupy all of mainland Australia and are currently the most common cause of snakebites and fatalities [1, 2, 4, 5, 7, 8]. These snakes are adapting to urban habitats and are now common in many cities. They vary widely in color and size; some exceed 2 m in length (Figs. 2, 3, 4, 5, 6, 7, and 8) [1, 2, 4].

Tiger Snake Group. The tiger snake group includes the tiger snakes, genus *Notechis* (Figs. 9, 10, 11, 12, and 13); the rough-scaled snake, *Tropidechis carinatus* (Figs. 14 and 15); the copperheads, genus *Austrelaps* (Figs. 16, 17, and 18); the broad-headed snakes, genus *Hoplocephalus* (Figs. 19, 20, 21, and 22); and technically, several genera of smaller elapids of little medical significance [1, 2, 4, 5]. These snakes range from northeastern mainland Australia, down the east coast, across the southern mainland, to southern islands, including Tasmania, and are the second most important cause of snakebites and fatalities [1, 2, 4]. Note that the nonvenomous Natricid freshwater snake, *Tropidonophis mairii*, is sympatric with *Tropidechis carinatus*, and to the nonexpert looks very similar.

Black Snake Group. The black snake group, genus *Pseudechis*, contains a group of larger snakes, collectively ranging across almost all of Australia and responsible for numerous

snakebites but few deaths (Figs. 23, 24, 25, 26, 27, and 28) [1, 2, 4, 5]. Principal species include the mulga snake and the red-bellied black snake.

Death Adders. Death adders, genus *Acanthophis*, are restricted to parts of mainland Australia; are unique in appearance, with a viper-like form (Figs. 29 and 30), but have fared poorly since European settlement and are increasingly uncommon as a cause of snakebites and fatalities [1, 2, 4, 5].

Taipans. The two taipan species, genus *Oxyuranus*, represent the most dangerous of all snakes, combining large size (3 m), big fangs, copious amounts of toxic venom, and a rapid strike (Figs. 31, 32, and 33). These snakes are restricted to northern and parts of eastern coastal Australia (common taipan) and sparsely populated parts of inland Australia (inland taipan) and cause relatively few snakebites and only occasional deaths [1, 2, 4, 5]. Untreated taipan bites carry a lethality rate of greater than 70% [9].

New Guinea

The New Guinea fauna reflects historic land bridges with Australia. Most of the venomous snake fauna is shared (see Table 2) [3].

Non-front-Fanged Colubroid Snakes

Information about NFFC [6] snakes in New Guinea is essentially similar to Australia.

Elapids

Death Adders. Death adders are still common in New Guinea and are a major cause of snakebites and fatalities, particularly in highland areas [3].

Taipans. The New Guinea subspecies of taipan is a major cause of snakebites and fatalities in the southern plains regions [3].

Black Snake Group. The endemic Papuan black snake and the mulga snake are found in southern plains regions but are no longer considered a common cause of bites [3].

Small-Eyed Snake. Unique to New Guinea and nearby islands, the small-eyed snake, *Micropechis ikaheka*, is now thought to cause significant numbers of bites and a few fatalities within its range [3].

Table 2 Medically Important Groups of Australian and Pacific Terrestrial Venomous Snakes, Including Species of Uncertain Medical Importance. Where distribution is listed as “Australia,” this does not imply occurrence throughout Australia, but rather that it occurs at least somewhere within Australia

Scientific name	Common name	Distribution
Colubridae		
<i>Boiga irregularis</i>	Brown tree snake	Northern Australia, New Guinea, adjacent Pacific islands
Homalopsidae		
<i>Cantoria</i> , <i>Enhydria</i> , <i>Foronidia</i> , <i>Myron</i> , <i>Cerberus</i> , <i>Pseudoferania</i> , <i>Heurnia</i> spp.	Water snakes (not sea snakes)	Northern Australia, New Guinea, adjacent Pacific islands
Elapidae		
Brown Snake Group		
<i>Pseudonaja affinis</i>	Dugite	Australia
<i>Pseudonaja aspidorhyncha</i>	Patch nosed brown snake	Australia
<i>Pseudonaja guttata</i>	Spotted brown snake	Australia
<i>Pseudonaja ingrami</i>	Ingram’s brown snake	Australia
<i>Pseudonaja inframacula</i>	Peninsular brown snake	Australia
<i>Pseudonaja mengdeni</i>	Western brown snake or gwardar	Australia
<i>Pseudonaja nuchalis</i>	Tropical brown snake	Australia
<i>Pseudonaja textilis</i>	Eastern brown snake	Australia, New Guinea
Tiger Snake Group		
<i>Notechis scutatus</i>	Common tiger snake, black tiger snake (several subspecies)	Australia
<i>Tropidechis carinatus</i>	Rough-scaled snake	Australia
<i>Austrelaps superbus</i>	Lowland copperhead	Australia
<i>Austrelaps ramsayii</i>	Highland copperhead	Australia
<i>Austrelaps labialis</i>	Pygmy copperhead	Australia

(continued)

Table 2 (continued)

Scientific name	Common name	Distribution
<i>Hoplocephalus bungaroides</i>	Broad-headed snake	Australia
<i>Hoplocephalus bitorquatus</i>	Pale-headed snake	Australia
<i>Hoplocephalus stephensi</i>	Stephen’s banded snake	Australia
<i>Paroplocephalus atriceps</i> ^a	Lake Cronin snake	Australia
<i>Cyrtophis</i> (<i>Rhinoplocephalus</i>) <i>nigrescens</i> ^b	Eastern small-eyed snake	Australia
Black Snake Group		
<i>Pseudechis australis</i>	Mulga snake or king brown	Australia, New Guinea
<i>Pseudechis butleri</i>	Butler’s mulga snake	Australia
<i>Pseudechis colletti</i>	Collett’s snake	Australia
<i>Pseudechis guttatus</i>	Spotted black snake	Australia
<i>Pseudechis papuanus</i>	New Guinea black snake	New Guinea
<i>Pseudechis porphyriacus</i>	Red-bellied black snake	Australia
<i>Pseudechis rosignolii</i>	Papuan dwarf mulga snake	New Guinea
<i>Pseudechis weigeli</i>	Pygmy mulga snake	Australia
Death Adder Group		
<i>Acanthophis antarcticus</i>	Common death adder	Australia
<i>Acanthophis hawkei</i>	Barkly tableland death adder	Australia
<i>Acanthophis cryptamydros</i>	(New species – not yet allocated)	Australia
<i>Acanthophis laevis</i>	New guinea death adder	New Guinea
<i>Acanthophis praelongus</i>	Northern death adder	Australia
<i>Acanthophis pyrrhus</i>	Desert death adder	Australia
<i>Acanthophis rugosus</i>	Papuan death adder	New Guinea, Australia
<i>Acanthophis wellsei</i>	Pilbara death adder	Australia

(continued)

Table 2 (continued)

Scientific name	Common name	Distribution
Taipan Group		
<i>Oxyuranus scutellatus</i>	Common taipan	Australia, New Guinea
<i>Oxyuranus microlepidotus</i>	Inland taipan	Australia
<i>Oxyuranus temporalis</i>	Central ranges taipan	Australia
Miscellaneous		
<i>Micropechis ikaheka</i>	New Guinea small-eyed snake	New Guinea, including Bougainville
<i>Toxicocalamus loriae</i> ^c	Loria forest snake	New Guinea
<i>Salomonelaps par</i> ^c	Solomons coral snake	Islands North of Bougainville, Solomon islands
<i>Loveridgelaps elapoides</i> ^c	Solomons small-eyed snake	Solomon islands
<i>Parapistocalamus hedigeri</i> ^c	Hediger's coral snake	Bougainville Island
<i>Aspidomorphus</i> spp. ^c	New Guinea crowned snakes	New Guinea, Moluccas
Sea snakes		
	Numerous species	Throughout Indo-Pacific waters, near land or reefs; one pelagic species

^aThe medical significance of envenoming by this rarely encountered snake is based on a single case report, where the patient developed procoagulant (defibrination) type coagulopathy, similar to envenoming by the closely related *Hoplocephalus* spp.

^bThere is one reported fatal case of envenoming by this species. The patient developed severe systemic myolysis, and myotoxins were subsequently found in the venom. This is not a rare snake, but no other cases of envenoming are reported

^cThese snakes are generally small; little or nothing is known of their venom; and for most species, no bites are recorded. They are of uncertain medical importance and are not included in subsequent tables. Of the species for which bites are recorded, none were fatal, and local swelling was the most common effect. This does not exclude the possibility, however, that a large specimen might cause severe envenoming, especially in a child

Brown Snakes. A few specimens of Australian brown snakes are reported from southern New Guinea, but they are not a major cause of snake-bites at present. It is unclear if they are native or if they were accidentally introduced [3].

Other Species

Several other species of lesser or uncertain medical significance occur in New Guinea (see Table 2).

Pacific

Most Pacific islands are without terrestrial snakes, or the snake fauna is limited to minor colubrid species, but sea snakes abound in most areas.

Non-front-Fanged Colubroid Snakes

The most important NFFC snake in the Pacific, the Australian brown tree snake, *Boiga irregularis*, was accidentally introduced to islands such as Guam during World War II [6]. Although this snake is not lethal, lack of predators has resulted in a population explosion, a consequence of which is a far higher rate of bites than seen in New Guinea or Australia. Human infants, in particular, may develop significant nonlethal envenoming when bitten [6].

Elapids

Apart from the presence of death adders and the small-eyed snake on a few islands near New Guinea and a few lesser species (see Table 2), medically significant elapids in the Pacific are restricted to the abundant sea snakes.

Venoms

As with other snakes, the medically significant snakes of the Australian and Pacific region possess complex, multicomponent venoms with a variety of clinical effects [1, 4, 5, 9–11]. These effects are overwhelmingly systemic rather than local, however. A summary of activities for each snake is given in Table 3.

Fig. 3 Eastern brown snake, *Pseudonaja textilis* (Copyright © Dr. Julian White)

Fig. 4 Juvenile eastern brown snake. Note classic black markings on the back of the head and adjacent neck (Copyright © Dr. Julian White)

Neurotoxins

Neurotoxins are the classic toxins of elapid snakes, and they are well represented within the Australian and related fauna [1, 5, 9]. They are all paralytic neurotoxins active at the neuromuscular junction [12].

Presynaptic Neurotoxins

Presynaptic neurotoxins are phospholipase A_2 toxins of variable size, ranging from approximately 10 to 88 kd [1, 5, 9]. Some have myotoxic activity in addition to causing progressive damage to the terminal axon of the neuromuscular junction. They initially cause acetylcholine release, then destruction of synaptic vesicles and

Fig. 5 Western brown snake, *Pseudonaja aspidorhyncha* (Copyright © Dr. Julian White)

Fig. 8 Peninsular brown snake, *Pseudonaja inframacula* (Copyright © Dr. Julian White)

Fig. 6 Western brown snake, different coloring (Copyright © Dr. Julian White)

Fig. 7 Dugite, *Pseudonaja affinis* (Copyright © Dr. Julian White)

mitochondrial structures, causing irreversible cessation of signal function [9].

Postsynaptic Neurotoxins

Most venoms containing presynaptic neurotoxins also contain postsynaptic toxins [9]. These toxins competitively bind to the acetylcholine receptor on the muscle end plate, blocking signal reception and causing paralysis, which is potentially reversible.

Myotoxins

The myotoxic activity in Australian snake venoms is mediated by modified phospholipase A₂ toxins, a few of which are also presynaptically active [9, 12]. Only skeletal muscle is affected to any significant degree, and the effect is predominantly systemic rather than local in the bitten area.

Procoagulants, Anticoagulants, and Hemorrhagins

Australian snake venoms are a rich source of potent procoagulants, mostly prothrombin converters, causing a brief period of thrombosis, followed by prolonged profound defibrination [1, 4, 9, 13]. Only a few species have clinically

Fig. 9 Distribution of tiger snakes, *Notechis spp.*, in Australia (Copyright © Dr. Julian White)

Fig. 10 Common tiger snake, *Notechis scutatus scutatus* (Copyright © Dr. Julian White)

Fig. 11 Common tiger snake, unbanded brown color phase, *Notechis scutatus scutatus* (Copyright © Dr. Julian White)

apparent anticoagulants [9, 13]. Hemorrhagins, although suspected for some species, have not been definitively isolated so far. The massive hemorrhagic effect seen with some viper venoms is not apparent with these elapid venoms.

Procoagulants

The potent prothrombin converters in some Australian snake venoms are extraordinarily

potent coagulants in vitro, but in vivo they usually are not associated with detectable thrombosis [1, 4, 9, 12, 13]. Rather, they are associated with rapid, often complete defibrination and hyperfibrinolysis, resulting in potentially lethal bleeding from any damaged vessels. These procoagulants are of Group C and D, varying in size from about 58 kd to greater than 200 kd [13].

Fig. 12 West Australian tiger snake, *Notechis scutatus occidentalis* (Copyright © Dr. Julian White)

Fig. 13 Black tiger snake (Flinders Ranges), *Notechis scutatus ater* (Copyright © Dr. Julian White)

Anticoagulants

Still poorly characterized, true anticoagulants of clinical significance are restricted to only some *Pseudechis* spp. and are only rarely associated with major bleeding [4, 12, 13].

Hemorrhagins

Hemorrhagins are unproven for any Australian venom, although they have been clinically suspected for at least the New Guinea taipan venom [1]. However, another explanation for the gingival bleeding often seen with taipan envenoming in New Guinea is that poor oral hygiene leaves numerous small potential oral bleeding points that become obvious once

defibrination and hyperfibrinolysis occurs, preventing effective hemostasis at these otherwise minor areas of gingival damage.

Nephrotoxins

Nephrotoxins are unproven for any Australian snake venom, although they have been clinically suspected for at least brown snake venom [1]. Nephrotoxicity is more likely a secondary effect of the disseminated microangiopathic hemolytic anemia that can occur in some envenomed patients [4, 8, 12]. The latter condition is characterized by intravascular hemolysis, anemia, thrombocytopenia, and renal failure, similar in presentation to thrombotic thrombocytopenia and hemolytic uremic syndrome, but the etiology of this condition in envenoming remains uncertain, since it appears more frequently following bites by species with low hemolytic potential in their venom [12–18].

Necrotoxins

There is no evidence of significant necrotoxic activity in any Australian snake venom, although a few, notably *Notechis* spp., may cause minor local tissue injury in certain circumstances [9].

Pathophysiology of Envenoming

Route and Onset

Most cases of snakebite follow subcutaneous injection of venom through one or two fangs, the quantity of venom injected being highly variable within a species and between species and genera (Table 4) [10]. Major venom components are generally of moderate to large size, mostly greater than 10 kd, and seem to be transported principally from the bite site via lymphatics [19]. Pressure immobilization first aid may effectively retard venom movement completely and delay onset of systemic envenoming until removed [20], whereupon rapid, severe systemic envenoming may

Fig. 14 Distribution of rough-scaled snake, *Tropidechis carinatus* (Copyright © Dr. Julian White)

Fig. 15 Rough-scaled snake, *Tropidechis carinatus* (Copyright © Dr. Julian White)

ensue in less than 30 min [1, 4, 5]. Without effective first aid, envenoming usually manifests within 30 min, although certain effects take longer to appear. In adults particularly, potentially life-threatening systemic envenoming, notably coagulopathy, may occasionally develop in the absence of major symptomatology and may only be detected by laboratory testing [11]. Occasionally, envenoming may be delayed by many hours, however, even without first aid.

Mechanisms

Paralysis

Presynaptic and postsynaptic flaccid paralysis is mediated through effects at the neuromuscular junction [1, 11, 12]. The neurotoxins first must traverse from the bite site to the circulation, via the lymphatics, then exit into the extravascular space to reach their target sites, a process easily subject to delays. For presynaptic neurotoxins, there is a latency period of at least 60 min from the time the neurotoxin reaches the target site (terminal axon cellular membrane, NMJ) and binds, to the time neurotransmission ceases [9]. This may explain why paralysis is unlikely to be evident in the first 60 min after the bite and is often apparent only several hours later.

When paralysis has been established, the half-life of the neurotoxins, generally unknown, may have little influence anyway, particularly for pre-synaptic neurotoxins. When these have caused damage to the terminal axon at the neuromuscular junction, recovery depends on cell regeneration, a process that may take days, weeks, or months [9, 11].

Fig. 17 Common copperhead, *Austrelaps superbus* (Copyright © Dr. Julian White)

Fig. 18 Pygmy copperhead, *Austrelaps labialis* (Copyright © Dr. Julian White)

Myolysis

The precise mechanism of myolysis induced by Australian snake venom toxins is poorly understood, but experimentally these toxins rapidly cause muscle cell damage when they have reached their target site, a process that, as with the neurotoxins, may be delayed for 1 or more hours [1, 9, 11]. Complete destruction of affected muscle cells occurs within 24–72 h, but the

basal lamina is unaffected, and myoblasts quickly begin the rebuilding process, resulting in progressive muscle reconstitution over about 4 weeks [9]. There is experimental evidence that only slow-twitch muscle fibers regenerate [9].

Fig. 20 Broad-headed snake, *Hoplocephalus bungaroides* (Copyright © Dr. Julian White)

Fig. 21 Pale-headed snake, *Hoplocephalus bitorquatus* (Copyright © Dr. Julian White)

Coagulopathy

The prothrombin converters reach their target as soon as they enter the circulation, a process that may occur within 10–20 min of the bite, unless effective first aid is used [1, 9, 11, 13, 21]. Coagulopathy, in this case defibrination, occurs in less than 30 min in some cases [11]. Research in dogs suggests that with high venom loads, there may be a brief but significant period of

thrombosis, before onset of prolonged and profound defibrination [22]. Fibrinolysis takes several minutes to become established after onset of fibrin formation. During this time, significant thrombi may form, potentially occluding crucial vessels, such as coronary arteries; this may explain the apparent early, often lethal cardiac collapse associated with some severe brown snake bites [4]. By the time an autopsy is

performed, hyperfibrinolysis will have ensured removal of all thrombi.

The duration of the prolonged defibrination phase is variable. For tiger snakes, even without treatment, it may last only 15–18 h, but for brown snakes and taipans, it may persist for more than a day if not treated [4]. Untreated coagulopathy is associated with sometimes severe, persistent bleeding from all wounds, including iatrogenic wounds, such as venipuncture sites and

intravenous line insertions [4, 11]. Lethal intracranial hemorrhages occur, although infrequently [4, 23]. The addition of external coagulation factors (e.g., fresh frozen plasma or cryoprecipitate) as treatment can worsen the coagulopathy if active venom procoagulant is still circulating. This may occur if insufficient antivenom has been given [1, 4].

The true anticoagulant venoms rarely cause severe effects, although they can rapidly produce gross abnormalities in clotting tests [1, 4]. Because their effect is purely inhibitory, however, without destruction of clotting factors, reversal of anticoagulation is rapid after antivenom therapy. The duration of the anticoagulant effect, if left untreated, is not known, although it is unlikely to extend more than 24–48 h.

Renal Damage

Although a primary nephrotoxic effect is suspected for brown snake venom, most cases of renal damage after Australian snakebite are probably secondary to some other process, such as myolysis with myoglobinuria, severe coagulopathy, intravascular hemolysis, or a hypotensive episode [1, 4]. The depth and duration of

Fig. 22 Stephen's banded snake, *Hoplocephalus stephensi* (Copyright © Dr. Julian White)

Fig. 23 Distribution of mulga snakes, *Pseudechis australis* and *Pseudechis butleri* (Copyright © Dr. Julian White)

renal damage are highly variable, ranging from a mild-to-moderate increase in serum creatinine levels and normal urine output to oliguric or anuric renal failure, often associated with acute tubular necrosis, to rare instances of permanent renal damage, renal cortical necrosis. Only renal cortical necrosis routinely results in long-term problems.

Fig. 24 Mulga snake, *Pseudechis australis* (Copyright © Dr. Julian White)

Clinical Presentation of Envenoming

The rate of envenoming is highly variable (Table 5); many, if not most, Australian snakebites result in no or minimal envenoming and do not require antivenom therapy [1, 4]. It is difficult to determine initially, however, if the bite will be minor or major because the local effects of envenoming, in contrast to snakebite in other parts of the world, are often minor and give no indication of forthcoming systemic problems. It follows that all suspected snakebites in the Australian region should be assumed to be major until clearly shown to be otherwise [1, 4].

Local Effects

Local effects vary from nil to minimal (e.g., brown snakes); to local pain, bruising, and mild edema (e.g., tiger snakes); to extensive local pain and edema (e.g., mulga and black snakes) (Table 6) [1, 4, 11]. Bite marks vary from invisible tiny punctures or scratches to obvious single or multiple fang punctures or scratches (Figs. 34, 35, and 36).

General Systemic Effects

The general effects of systemic envenoming are easily confused with the effects of anxiety, itself a likely response to suspected snakebite [1, 4, 11]. When venom has been absorbed and traverses the lymphatics, draining lymph nodes may become enlarged or tender. The patient may

develop a severe headache, nausea, persistent vomiting, abdominal pain, dizziness, blurred vision, and nonspecific (i.e., nonneurotoxic) weakness [1, 4, 11]. Early collapse is common, usually associated with spontaneous recovery after only a few minutes [1, 4, 11]. Particularly in children, generalized convulsions may occur [1, 4].

Fig. 28 Red-bellied black snake, *Pseudechis porphyriacus* (Copyright © Dr. Julian White)

Fig. 29 Distribution of Australian death adders, *Acanthophis* spp. (Copyright © Dr. Julian White)

Specific Systemic Effects

Australian snakebite is strongly associated with potentially lethal-specific systemic effects (Table 7).

Neurotoxic Paralysis

Progressive flaccid paralysis, ending after 18–30 h in complete respiratory paralysis and death due to respiratory failure, previously was the classic cause of snakebite death [11]. With modern

intensive care unit facilities, such respiratory deaths should now be rare. The first signs of flaccid paralysis are seen in the cranial nerves, at least 1 h (sometimes many hours) postbite [1, 4, 11]. Ptosis usually is seen first (Fig. 37), followed by partial ophthalmoplegia (diplopia) (Fig. 38), then complete ophthalmoplegia with fixed forward gaze, often with fixed dilated pupils. Ophthalmoplegia is accompanied by dysarthria, dysphagia, tongue weakness, slack facies, and drooling. Loss of airway protection at this stage

Fig. 30 Common death adder, *Acanthophis antarcticus* (Copyright © Dr. Julian White)

Fig. 31 Distribution of Australian taipans, *Oxyuranus* spp. (Copyright © Dr. Julian White)

may force early intubation. Untreated, the paralysis may extend to encompass limb weakness to complete paralysis, with loss of deep tendon reflexes. Paralysis of respiratory muscles, particularly the diaphragm, may take 18–30 h postbite to develop (Fig. 39).

Myolysis

Myolysis takes 1 or more hours postbite to become evident, as development of muscle pain, tenderness, and nonspecific weakness, usually

with some degree of myoglobinuria (Fig. 40) and always with a major rise in plasma creatine phosphokinase (CP) [1, 4, 11]. Occasionally, myolysis becomes evident only 1–2 days postbite. Major myolysis is sometimes associated with secondary renal failure and severe hyperkalemia, with concomitant, potentially lethal cardiac problems, but severe myolysis and myoglobinuria can occur without evidence of renal damage.

An intriguing single case of apparently localized myolysis in the bitten limb of a previously

Fig. 32 Common taipan, *Oxyuranus scutellatus* (Copy-right © Dr. Julian White)

Fig. 33 Inland taipan, *Oxyuranus microlepidotus* (Copy-right © Dr. Julian White)

bitten keeper of death adders (*Acanthophis* spp.), reaching a peak CK of about 4,900IU/l, has been reported [24]. No systemic effects developed, other than the rise in CK and there was marked pain and swelling of the bitten limb. IgG antibodies to death adder venom had been detected after a previous bite (not treated with antivenom), and no circulating venom was detected on this subsequent bite. It is unclear if circulating antibodies against the venom prevented systemic envenoming in this case, but clearly did not prevent significant local envenoming.

Coagulopathy

Coagulopathy, even complete defibrination, although usually found in association with

Table 3 Summary of principal venom activities for each group of snakes^a

Snake group	Venom activity
Colubridae	
Brown tree snake	Partially characterized; no neurotoxic, myotoxic, or procoagulant activity in mammals reported
Elapidae	
Brown snake group (<i>Pseudonaja</i> spp.)	Procoagulants, pre- and postsynaptic neurotoxins, possible nephrotoxin
Tiger snake group (<i>Notechis scutatus</i> , <i>Tropidechis carinatus</i>)	Procoagulants, pre- and postsynaptic neurotoxins, myotoxins
Copperhead subgroup (<i>Austrelaps</i> spp.)	Pre- and postsynaptic neurotoxins, anticoagulants, myotoxins (uncertain clinical significance)
Broad headed snake subgroup (<i>Hoplocephalus</i> spp., <i>Paroplocephalus atriceps</i>)	Procoagulants
Black snake group (<i>Pseudechis</i> spp.)	Anticoagulants, myotoxins, neurotoxins (Papuan black snake)
Death adder group (<i>Acanthophis</i> spp.)	Pre- and postsynaptic neurotoxins
Taipan group (<i>Oxyuranus</i> spp.)	Procoagulants, pre- and postsynaptic neurotoxins, myotoxins
New Guinea small-eyed snake (<i>Micropechis ikaheka</i>)	Anticoagulant, myotoxin, postsynaptic neurotoxin
Sea snakes	Postsynaptic neurotoxins, myotoxins

^aNot all species in each group display all activities listed for that group

obvious general symptoms, such as headache and vomiting, may develop silently, particularly in adults, becoming apparent only when clotting tests are performed or when major bleeding manifests unexpectedly [1, 4, 11]. Some authors have labeled this venom-induced consumptive coagulopathy [8, 15, 18]. The classic sign of coagulopathy is a persistent oozing of blood not only from the bite site but also from venipuncture and intravenous insertion sites and from any recent wound (Fig. 41). Gingival bleeding can occur, notably in patients with poor oral hygiene.

Table 4 Average venom yields for selected major snake groups^a [10]

Snake group	Average venom yield (mg)
Colubridae	
Brown tree snake	1–10
Elapidae	
Brown snake group	2– > 20
Tiger snake group	5– > 50
Black snake group	30– > 180
Death adder group	80
Taipan group	>120
New Guinea small-eyed snake	Not well characterized
Sea snakes	2– > 30

^aAverages vary among species within group; average milked venom in dry weight

Table 5 Estimated average rate of medically significant Envenoming for Medically Important Snake Groups^a

New Guinea small-eyed snake	Not well characterized
Sea snakes	<20

^aFigures are only approximate and may vary among species in group

Intracranial bleeds or bleeds into major organs manifest as with any other cause of such bleeding. The clinician should beware of injudicious venous or arterial line insertions if coagulopathy possibly could be present and should avoid insertion or sampling from the subclavian, femoral, or jugular vessels (Fig. 42) [4]. Extended coagulation tests, repeated frequently, are the most useful determinant of coagulopathy [1, 4, 19]. The abnormalities detected depend not only on the severity of the envenoming but also on the type of snake and its venom constituents. Thrombocytopenia is not common and usually occurs either as an isolated

Table 6 Local effects at bite site for Medically Important Snake Groups

Snake group	Local effect of bite
Colubridae	
Brown tree snake	Mild-to-moderate swelling, ± blistering, without necrosis
Elapidae	
Brown snake group	Nil or minimal local pain, swelling, or erythema. Even severe bites may be virtually invisible and the patient unaware of bite
Tiger snake group	Tiger snakes and rough-scaled snakes generally cause painful bites with local erythema, ecchymosis, and swelling. Copperhead bites are less locally severe. Broad-headed snakes usually cause few local effects
Black snake group	Locally painful, usually with moderate-to-marked local, occasionally regional swelling. Papuan black snake causes less marked local swelling
Death adder group	Locally painful, but usually little local swelling or other visible effects, though at least 1 case reported with significant local swelling, pain and local myolysis despite absence of systemic envenoming [24]
Taipan group	Variable from minimal local effects to local pain, swelling, erythema, and slight ecchymosis
New Guinea small-eyed snake	Not well characterized
Sea snakes	Minimal local reaction

finding, or in patients developing a microangiopathic hemolytic anemia (triad of thrombocytopenis, intravascular hemolysis with anemia, and secondary renal failure), but secondary disseminated intravascular coagulation may occasionally occur [1, 4, 5, 11, 13–18].

Renal Damage

Renal damage usually is symptomatically silent. It is first announced by either a rising blood creatinine or by a falling urine output.

Other

Cardiac abnormalities are not common with Australian snakebite and when present are always

Fig. 34 Minimal local reaction at the bite site, as seen with brown snake bites. Minimal local effects can be associated with life-threatening systemic envenoming (Copyright © Dr. Julian White)

Fig. 35 Local erythema and bruising at the bite site, typical of tiger snake bites (Copyright © Dr. Julian White)

Fig. 36 Extensive local swelling, typical of mulga snake bites (Copyright © Dr. Julian White)

secondary, either to coagulopathy (early temporary thrombosis) or to myolysis (hyperkalemia). Although hypotension may occur, systemic envenoming usually is associated with hypertension. However, particularly for bites by brown snakes (*Pseudonaja* spp.), early collapse and cardiac arrest can occur and may be the commonest cause of snakebite fatality in Australia [4]. The etiology of this cardiac collapse remains uncertain. If adequate cardiopulmonary resuscitation (CPR) is provided, patients generally then respond and recover. An absolute lymphopenia is a common, although not universal, accompaniment of major systemic envenoming [25].

Diagnosis of Envenoming

The diagnosis of envenoming may be simple or difficult. The latter applies in children, who may not be able to give a history of a bite, and in adults, who may be bitten unawares, presenting later with general symptoms that could imply a wide array of diagnoses. The often trivial sometimes invisible bite marks may make correct diagnosis difficult, unless a high index of suspicion is maintained for snakebite.

History

The crucial points in history are the following:

Geographic location where a bite might have occurred

Table 7 Principal systemic effects for Medically Important Snake Groups

Snake group	Systemic effect
Colubridae	
<i>Boiga irregularis</i>	In infants only (Guam cases), mild flaccid paralysis (ptosis, lethargy, impaired standing/walking), rarely respiratory distress
Elapidae	
Brown Snake Group	
<i>Pseudonaja spp.</i>	Defibrination coagulopathy, \pm renal damage, only rarely paralysis, never myolysis
Tiger Snake Group	
<i>Notechis spp.</i>	Defibrination coagulopathy (resolves untreated after 15–18 h), pre- and postsynaptic flaccid paralysis (severe), severe myolysis, \pm renal damage
<i>Tropidechis carinatus</i>	As for <i>Notechis</i> spp.
<i>Austrelaps spp.</i>	Poorly defined; flaccid paralysis dominant feature
<i>Hoplocephalus spp.</i>	Defibrination coagulopathy only
<i>Paroplocephalus atriceps</i>	Defibrination coagulopathy only
<i>Rhinoplocephalus nigrescens</i>	Myolysis only, \pm secondary renal damage
Black Snake Group	
<i>Pseudechis australis</i> , <i>Pseudechis butleri</i> , <i>Pseudechis colletti</i>	Anticoagulant coagulopathy, severe myolysis, rarely mild flaccid paralysis (ptosis only)
<i>Pseudechis papuanus</i>	Coagulopathy, thrombocytopenia, flaccid paralysis
<i>Pseudechis guttatus</i> , <i>Pseudechis porphyriacus</i>	Anticoagulant coagulopathy (not all cases), mild-to-moderate myolysis (rarely severe). Recurrent severe vomiting is particularly prominent with significant systemic envenoming by these snakes
Death Adder Group	
<i>Acanthophis spp.</i>	Predominantly postsynaptic flaccid paralysis only, but some presynaptic paralysis may

(continued)

Table 7 (continued)

Snake group	Systemic effect
	occur in a minority of cases. In New Guinea, mild anticoagulant coagulopathy may occur. Though apparently localized to the bitten limb, systemic rise in CK (to $\sim 4,900$ IU/l) detected in a single reported case, without other evidence of systemic envenoming [24]
Taipan Group	
<i>Oxyuranus spp.</i>	Defibrination coagulopathy, hemorrhage, pre- and postsynaptic flaccid paralysis (rapid, severe), occasionally moderate myolysis, \pm renal damage
Miscellaneous	
<i>Micropechis ikaheka</i>	Poorly defined due to paucity of reported cases, but expect anticoagulant coagulopathy, bleeding, flaccid paralysis, possibly myolysis, \pm secondary renal damage
Sea Snakes	
	Varies with species, but flaccid postsynaptic paralysis and/or myolysis, \pm secondary renal damage

Circumstances surrounding definite or suspected bite

Number of bites

Activity before applying first aid

Type and effectiveness of first aid

Timing of onset and nature of any symptoms that might reflect envenoming

Past medical history, including any past exposure to antivenom

Medications, particularly those affecting blood clotting

Examination

The crucial points in examination are the following:

Fig. 37 Early ptosis, the first sign of developing paralysis (tiger snake bite) (Copyright © Dr. Julian White)

Fig. 38 Partial ophthalmoplegia with divergent squint and diplopia. Ptosis is also present (death adder bite) (Copyright © Dr. Julian White)

Fig. 39 Complete flaccid paralysis, requiring prolonged mechanical respiratory support (on ventilator for 5 weeks; taipan bite) (Copyright © Dr. Julian White)

Local bite site – presence of bite marks (especially multiple bites), persistent bleeding, edema, and bruising

Tender or swollen draining lymph nodes

Presence of signs of paralysis, myolysis, or coagulopathy

Laboratory Tests

The crucial laboratory tests are the following:

Snake venom detection (Australia and New Guinea only)

Extended coagulation studies (prothrombin time or international normalized ratio [PT/INR]), activated partial thromboplastin time [aPTT], fibrinogen level, and fibrin degradation products/D dimer (FDP/XDP) [1, 4, 26]. Note that point of care INR testing may give erroneous results with snakebite coagulopathy, potentially indicating a normal INR and therefore absence of coagulopathy in a patient with severe defibrination coagulopathy [4, 27, 28].

Complete blood count (platelet count, absolute lymphocyte count)

Electrolytes and renal function

CK

In a country hospital without ready access to a laboratory, a reasonable assessment can be made with the following tests:

Fig. 40 Red urine indicative of myoglobinuria (mulga snake bite) (Copyright © Dr. Julian White)

Fig. 41 Persistent blood ooze from venous line site, indicating coagulopathy (inland taipan bite) (Copyright © Dr. Julian White)

Snake venom detection

Whole-blood clotting time (preferably 20 min whole-blood clotting test, using a glass vessel)

Dip-stick urine analysis

Fig. 42 Extensive hematoma extending from failed jugular line insertion in the neck, in a patient with severe coagulopathy (taipan bite) (Copyright © Dr. Julian White)

If initial tests are normal, they must be repeated to eliminate delayed envenoming. As a general rule, tests should be done on presentation prior to removing and first aid (except for arterial tourniquets which require urgent removal in most cases) and if normal and the patient is asymptomatic and shows no physical evidence of envenoming (e.g. no neurotoxic signs), then remove first aid and retest 1 h later and if normal and no clinical evidence of envenoming, again at about 6 and 12 h postbite [4, 26] (Grade II-2 recommendation). If tests are abnormal, a different test regimen is required (see later in treatment section).

Interpreting Laboratory Tests

Laboratory tests can be crucial in determining if systemic envenoming is present or if snakebite is likely, and it may assist in determining the type of snake.

Snake Venom Detection Interpretation of snake venom detection tests is discussed subsequently.

Coagulation Tests Significantly prolonged PT/INR (INR 2 to >12) and activated partial thromboplastin time (aPTT) plus decreased fibrinogen (often undetectable) and increased FDP/D-dimer (often grossly increased) usually with normal platelet count indicate defibrination coagulopathy (brown snakes, tiger snakes,

rough-scaled snakes, broad-headed snakes, taipans) [1, 4].

Significantly prolonged PT/INR (INR 2 to >12) and/or prolonged activated partial thromboplastin time; and normal fibrinogen, FDP/D-dimer, and platelets indicates anticoagulant coagulopathy (mulga snake, Collett's snake, Papuan black snake) [1, 4].

If a laboratory able to perform coagulation tests is not available, such as in a small country hospital, then a potential alternative is the 20-min whole blood clotting tests (20WBCT) [4, 29]. This simple test requires a clean glass vessel in which is placed about 2–3 ml of the patient's venous blood. This is gently inverted once, then left to stand for 20 min, after which it is again gently inverted looking for a clot. If the blood remains fluid, without a clot, the test is positive, indicating a coagulopathy may be present. It is always advisable to perform a control at the same time with an identical second container and blood from a presumed normal person (relative or staff member). The 20WBCT is the standard for detecting snakebite coagulopathy in many high risk regions of the world and has been considered reliable [29], despite a recent study questioning reliability (this study was not using Australian snakebite cases) [30].

Absolute Lymphocyte Count Absolute lymphopenia is a feature of significant systemic envenoming by potentially all Australian dangerous snakes, but particularly tiger snakes. It is seen usually in the first 12 h after onset of envenoming [25].

Electrolytes and Renal Function Rising serum creatinine and urea indicate developing renal damage.

Hyperkalemia usually indicates severe myolysis, mostly in association with secondary renal failure [4].

Creatine Phosphokinase CPK elevation may indicate myolysis; values greater than 5,000 U/L almost always are due to myolysis in a snakebite patient. Values greater than one million U/L may occur. Peak myolysis may not be seen for 72 h, occasionally longer [4].

Venom Detection

The bioCSL Ltd. (now Seqirus) Snake Venom Detection Kit (SVDK) is an enzyme-linked sandwich immunosorbent assay-based test, unique to Australia and New Guinea, capable of detecting nanogram-quantities of major snake venoms in samples from the bite site or urine (blood is not as reliable) [4, 5, 31]. The SVDK contains five separate wells, each one corresponding to a snake venom immunotype, corresponding to the five types of monospecific antivenoms. The best sample is a swab from the bite site, first moistened with the SVDK fluid, but in the presence of systemic envenoming, urine also may be used [4]. A positive result indicates that snake venom is probably present in the sample and indicates the most likely type of snake venom immunotype, but it is not an indication to use antivenom; it merely indicates which is the most appropriate antivenom, should this be required on clinical or laboratory grounds [4]. A negative result indicates only the test was negative; it does not exclude snakebite [4]. Thus, the purpose of the kit is to choose the most appropriate monospecific antivenom to use in an envenomed patient. It is not a screening test for snakebite. The SVDK is not readily available in New Guinea.

Diagnostic Algorithms

Diagnostic algorithms have been developed for Australia to assist in determining the most likely snake in cases with significant systemic envenoming (Figs. 43 and 44) [4]. These algorithms are useful when venom detection has failed or is not available, or when the result is suspect, but more commonly and importantly they help support the SVDK result. If the algorithm and the SVDK give a similar result, then the type of snake can be confidently assumed, but if they give disparate results expert advice should be sought via bioCSL Ltd. (now Seqirus) [4]. Similar to all such diagnostic algorithms, these cannot cater to all eventualities and should be used with wisdom and caution.

Fig. 43 Diagnostic algorithm for Australian snakebite, based on local effects (Copyright © Dr. Julian White)

Differential Diagnosis

Snakebite should be considered in the differential diagnosis of any unexplained flaccid paralysis, myolysis, coagulopathy, unexpected major hemorrhage, renal failure, cardiac collapse, general collapse, or convulsions, where snakebite is a possibility, even if there is no history of exposure to a snake [1, 4]. Snakebite is not limited to rural areas or outside buildings; dangerous snakes regularly enter gardens and homes in even the largest Australian cities.

Treatment of Envenoming

Indications for ICU Admission in Australian and Pacific Snake Envenoming
Every case of significant systemic envenoming with any of the following:

Any degree of flaccid paralysis beyond simple ptosis

(continued)

Fig. 44 Diagnostic algorithm for Australian snakebite based on systemic effects. FDP/XDP, fibrin degradation product/D dimer (Copyright © Dr. Julian White)

Any established defibrination or anticoagulant coagulopathy

Any major secondary problems, such as major bleeding or anuric renal failure

The following cases are best managed in an emergency department short stay ward, or high-dependency unit setting or, if unavailable, in an intensive care unit:

Any case of suspected snakebite, even if initially no evidence of systemic envenoming

Although most snakebites in Australia are likely to prove minor, this cannot be reliably predicted within the first few hours. All cases of definite or suspected snakebite should be considered potentially major and lethal until clearly shown to be otherwise [1, 4].

First-Aid Considerations

First aid for snakebite in Australia and New Guinea is the pressure bandage and immobilization method (PBI), designed to retard venom

movement via the lymphatics [4, 20] (Grade II-2, 3 recommendation). It has been shown to be effective in a monkey model and anecdotally in human cases of envenoming, although the method remains unproven by clinical trial [4, 5, 11, 20]. Nevertheless, the pressure bandage immobilization method appears comparatively safe and effective compared with the alternatives used in most other parts of the world. The technique involves the application of a broad bandage over the bitten area, at about the same pressure as used for a sprain. The bandage is extended to cover as much of the limb as possible, then the limb is immobilized using a splint. Correctly applied, this first aid can be left on for several hours, until the patient is in a hospital and can be treated with appropriate antivenom, if required. Recent research has suggested that an elastic bandage is more likely to provide effective pressure than the crepe bandage originally used in development of the technique [32]. Because of venom detection, the bite would should not be cleaned or moistened. A modified method using just a local pressure pad has been tested and recommended in Myanmar, but not tested or recommended in Australia; therefore, the reliability of this method remains uncertain for Australian snakebite [33]. A further additional technique using pharmacological methods, applied topically, to slow lymphatic flow, has been tested experimentally with success, but remains unproven clinically [34].

However, given that most snakebite fatalities in Australia are now due to prehospital cardiac collapse and arrest, with inadequate CPR, it could be argued that the most critical first aid for snakebite is CPR (where indicated), the application of PBI.

When the patient is already in the hospital, the issues with first aid are when to apply it in the hospital and, more commonly, when to remove it. First aid should be applied in a hospital only if the following apply (Grade III recommendation) [4]:

1. It is less than 15 min postbite.
2. There are no facilities to give antivenom, and the patient will be transferred elsewhere.
3. The patient already has severe, life-threatening envenoming.

First aid should be removed in the hospital only when the following have been done:

1. An intravenous line has been inserted, with an initial intravenous fluid load.
2. The bandage over the bite site has been cut away, the wound has been inspected, and the wound has been moist-swabbed (swab stick moistened with diluent) for venom detection.
3. Blood has been taken for relevant tests (coagulation, complete blood count, electrolytes, renal function, CPK).
4. A relevant history has been obtained.
5. The patient has been examined for signs of envenoming.
6. The results of venom detection and blood tests have been received and evaluated.
7. An expert in envenoming has been consulted (if appropriate).
8. Initial antivenom therapy has been started, if required (it is not required in most cases).

The first aid should not be left on when the above-listed requirements are fulfilled. Prolonged use of first aid may cause local skin injury (notably with tiger snake bites).

Basic Treatment

As noted earlier, after vital functions are secured (rarely an issue), initial management is based on obtaining intravenous access; ensuring adequate hydration; establishing a firm diagnosis, including assessment of the extent of any envenoming; and starting specific treatment if required [4] (Grade III recommendation). Because most cases of snakebite in Australia do not result in significant envenoming, initial tests are likely to be normal. Because delayed envenoming can occur, it is essential both that repeat tests be performed (as noted earlier) and that vital signs be assessed frequently, including checks for early paralysis, coagulopathy, and myolysis [4] (Grade III recommendation). Renal output should be monitored; if the output is in question, the patient should be catheterized, but otherwise avoid catheterization, especially if there may be coagulopathy.

Snakebite in New Guinea is different because a higher proportion of cases show significant envenoming, correct first aid is less likely to have been used, laboratory testing and antivenom may be unavailable except in a few major centers, and patients frequently present many hours postbite with major problems already evident.

Antivenom

The key decision in managing snakebite is if and when to give antivenom, then which type and how much. All cases with significant envenoming should be considered for antivenom therapy [1, 4, 5, 19] (Grade III recommendation). It is required in nearly all such cases, often proving lifesaving.

When to Use Antivenom

Antivenom should be used only in the presence of significant systemic envenoming, which may be defined as the presence of one or more of the following [1, 4, 19]:

- Flaccid paralysis (even just ptosis, unless this is the only sign and has been present >12 h)
- Myolysis (usually a CK >1,500 U/L or a rapidly increasing CK early after envenoming)
- Coagulopathy (usually any degree of defibrination, such as an INR >2, or any degree of true anticoagulation)
- Renal damage (an elevated and rising creatinine, even if still normal urine output)
- A clear history of collapse or convulsions after a witnessed snakebite by a dangerous species of snake (e.g., not a python bite).

General symptoms, such as headache, nausea, vomiting, and abdominal pain, although raising suspicions of significant envenoming, also may be due to anxiety and are not alone an indication that antivenom is required [1, 4]. Certain snakes, notably some or all *Pseudechis* spp. (mulga snakes, black snakes), can cause severe intractable vomiting that may be unresponsive to antiemetics, but responsive to antivenom [4]. A positive SVDK result from either the bite site or urine in

isolation is not an indication that antivenom is required (Grade III recommendation) [4]. Antivenom should be given as soon as safely possible when there is an indication that it is required [4].

Choosing the Right Antivenom

In contrast to some other regions, the choice of snake antivenom, although limited to one producer (bioCSL Ltd, Melbourne; now Seqirus), encompasses a variety of “monospecific” antivenoms, in addition to a polyvalent antivenom [4]. The latter covers all species but is the highest volume (increased risk of adverse reactions) and the highest cost and generally is used only if the type of snake is unknown and it is not practical to cover all possible species by mixing two monospecific antivenoms [4]. The available antivenoms and the species they cover are listed in Table 8. Because envenoming by some species may require the equivalent of multiple ampules of antivenom as an initial dose, the disadvantages of routinely using polyvalent antivenom are apparent. The dose of antivenom used in Australia has reduced substantially in recent years, and the high doses previously recommended [1] are no longer used [4], but there is ongoing controversy over how low the dose should be [4], with one group recommending a single vial is always sufficient, in every case [35], though even this group is now reporting cases which challenge the “one vial” recommendation [36]. Others, including the antivenom producer, consider such a restrictive minimal dose policy unwise and recommend slightly higher dose for certain antivenoms [4]. The reasoning for this is that it is best to cover for more severe outlier cases in selecting initial doses as it is these patients who are at highest risk and antivenom is most likely to be effective when given early. It is also known that some subspecies or races of particular snakes (notably some types of black tiger snake) require significantly increased doses of antivenom to cover their higher venom yield [1, 4].

Identifying which type of snake is responsible for the bite is the principal function of the SVDK [4]. This identification may be supported by the use of diagnostic algorithms, as discussed earlier [4]. Because color is variable and an unreliable

Table 8 Recommended doses of antivenom for patients with significant envenoming, based on type of snake^a

Snake	Starting dose of antivenom ^b
Colubridae	
<i>Boiga irregularis</i>	No AV available
Elapidae	
Brown Snake Group	
<i>Pseudonaja spp.</i>	1–2 vials CSL Brown Snake AV
Tiger Snake Group	
<i>Notechis scutatus</i> and most <i>Notechis ater</i> subspecies	1–2 vials CSL Tiger Snake AV
<i>Notechis ater serventyi</i> , <i>Notechis ater humphreysi</i>	2–4 vials CSL Tiger Snake AV
<i>Tropidechis carinatus</i>	1–2 vials CSL Tiger Snake AV
<i>Austrelaps spp.</i>	1 vial CSL Tiger Snake AV
<i>Hoplocephalus spp.</i>	1 vial CSL Tiger Snake AV
<i>Rhinoplocephalus nigrescens</i>	1 vial CSL Tiger Snake AV
Black Snake Group	
<i>Pseudechis australis</i> , <i>Pseudechis butleri</i> , <i>colletti</i>	1 vial CSL Black Snake AV
<i>Pseudechis guttatus</i> , <i>Pseudechis porphyriacus</i>	1–2 vials CSL Tiger Snake AV OR 1 vial of CSL Black Snake AV
Death Adder Group	
<i>Acanthophis spp.</i>	1 vial CSL Death Adder AV
Taipan Group	
<i>Oxyuranus spp.</i>	1 vial CSL Taipan or Polyvalent AV
Miscellaneous	
<i>Micropechis ikaheka</i>	1+ vials CSL Polyvalent Snake AV
Sea Snakes	
	1–3 vials CSL Sea Snake AV, or if unavailable, 3+ vials CSL Tiger Snake AV or CSL Polyvalent Snake AV

^aAll listed antivenoms (AV) are produced by bioCSL Ltd, Melbourne, Australia

^bFor all snakes, if insufficient specific AV is available, consider using bioCSL Polyvalent Snake Antivenom at the same dose (i.e., same number of vials) as for the specific antivenom. Dose given is initial dose only. Severe cases may require higher initial doses and possibly may require further doses after the initial dose, though repeat dosing is now uncommon to rare

indicator of species, the patient's identification of the snake, if offered, should be used only with great caution [4, 19]. An exception is a herpetologist bitten by a captive snake or a wild specimen during the course of capture; however, not all herpetologists are as reliable at identifying snakes as their confidence might suggest.

In New Guinea, assuming that antivenom is even available, the range of antivenoms is often limited to Death Adder and Polyvalent [37]. A new antitaipan antivenom is undergoing clinical trial and if successful may be approved [38–40]. Because death adders are distinctive snakes, a patient's confident assertion that the assailant was a death adder is usually correct. In all other circumstances, polyvalent antivenom should be used. In Indonesian New Guinea (Irian Jaya) and a few islands to the east, where death adders occur, Seqirus (bioCSL) antivenoms may be unavailable. Instead, local Indonesian antivenoms may be present. These are essentially useless for the snakes discussed in this chapter and should not be used, unless it is certain that the bite was from an Indonesian cobra (not likely in Irian Jaya, unless a captive specimen).

In Pacific islands with terrestrial snakes, envenoming does not warrant antivenom, or none is available (e.g., brown tree snake bite to an infant in Guam). For all areas where sea snakes are present, the optimal choice of antivenom is Seqirus (bioCSL) Sea Snake [4]. If it is unavailable, Seqirus (bioCSL) Tiger Snake or Polyvalent should be tried, at a ratio of 3 ampules for each ampule of Sea Snake antivenom that would have been indicated [4]. However, earlier research indicating these antivenoms may be effective against sea snake envenoming is no longer valid because of changes in the method of producing these antivenoms [4]. Currently it is unclear how effective, if at all, these antivenoms may be against sea snake envenoming, reinforcing the preferential use of specific Seqirus (bioCSL) Sea Snake AV [4].

Correct Dose

The initial dose of antivenom depends on the type of snake and the degree of envenoming. Although there are no absolutes in determining dose,

suggested guidelines are given in Table 8. Giving too low an initial dose is a common reason for failure of antivenom therapy [4, 19]. In New Guinea, where antivenom is in restricted supply, optimal doses may not be achievable. Often a single dose of one ampoule is all that is possible, though this does appear to be generally effective. Children require the same dose as adults [4].

How to Give Antivenom

Antivenom for snakebite should always be given intravenously, preferably diluted 1:10 in saline, Hartman's, or a similar solution (Grade III recommendation) [4, 19, 35]. The degree of dilution achievable is determined by the volume of antivenom and the size of the patient. Significant dilutions may be difficult to achieve with pediatric patients, with elderly patients with preexisting cardiac problems, or with high-volume antivenoms such as Polyvalent. The infusion should be started slowly, aiming to give the whole dose (even multiple ampoules) over 15–20 min (Grade III recommendation) [4, 35]. The clinician should always have epinephrine (adrenaline) ready to give, in case an anaphylactic/anaphylactoid reaction occurs. If available, a prepared epinephrine infusion may be suitable, with an infusion pump [4, 19].

When to Give More Antivenom

The initial dose may not be enough, but determining when and how much more antivenom to give is not always straightforward and repeat dosing is now uncommon to a rare event [4, 35]. For defibrination coagulopathy, enough antivenom has been given when fibrinogen levels start to rise, indicated by either an increase in the absolute value or by a decrease in the PT/INR [4]. However, this may take at least 6 h post antivenom, sometimes longer. Giving further antivenom prior to this is generally not justified [4]. It is not necessary to wait for return to normal values. In general, coagulation tests should be repeated at 1 h and 3 h and 6 h after completion of the initial dose of antivenom [4]. The first and second tests are to indicate trends, and the third test is to decide if further antivenom is needed. If the 6-h test

shows no change from complete defibrination, expert consultation should be sought to help guide whether further antivenom should be given in a dose similar to or slightly less than the initial dose (Grade III recommendation) [4]. Some authors consider that antivenom may be ineffective at reversing defibrination coagulopathy with Australian elapid snakebite and advocate that no antivenom should be given after the initial dose [35, 41–46]. While this view is not accepted by all experts in clinical toxinology, it is accepted that the high doses of antivenom previously used to treat defibrination coagulopathy are no longer appropriate and that repeat dosing should be the exception, not the rule [4]. Even if there is no change in laboratory clotting parameters 6 h post antivenom, if the patient is no longer showing evidence of active coagulopathy (failure to clot at venipuncture sites, continued oozing from all bleeding points such as gums, IV sites), then it is advisable to hold off on giving more antivenom and repeat coagulation testing again 1–3 h later (Grade III recommendation) [4]. Fresh frozen plasma or cryoprecipitate should not be given while there is active coagulopathy except if an uncontrolled and catastrophic hemorrhage is occurring [1, 4, 19]. The use of FFP after giving antivenom has been studied, and if given within 6 h of the bite it may make the coagulopathy worse, while if given more than 6 h post bite, it is not associated with improved patient outcomes, even though coagulation tests may return towards normal more rapidly [35, 47].

For myolysis, laboratory tests are less helpful in guiding further therapy. If there is a persistent significant increase in CPK after initial antivenom therapy, then giving further antivenom at a similar dose may be considered. However, evidence is equivocal about effectiveness of delayed antivenom in managing myolysis. One study indicated that for bites by high risk species for myolysis (black and mulga snakes, *Pseudechis* spp.), giving antivenom early (within first 6 h post bite) was associated with low incidence of myolysis, while antivenom given after 6 h had no effect on incidence or severity of myolysis [48,

49]. A more recent report indicates that use of early antivenom at a low dose may not protect against myolysis, in contrast to the earlier studies [36]. The author has had case experience indicating that late antivenom is associated with temporal improvement in both symptomatology and laboratory measures of myolysis and therefore generally recommends antivenom be considered in cases with ongoing severe myolysis (Grade III recommendation).

For postsynaptic paralysis, giving further antivenom may be considered if the initial dose fails to cause adequate reversal of signs [1, 4]. For presynaptic paralysis, there is little likelihood that antivenom would reverse established paralysis, so further antivenom therapy is pointless [1, 4].

For renal damage, the role of antivenom is uncertain. Because most renal damage is mediated through secondary effects, further antivenom is unlikely to result in benefit.

Antivenom Therapy Complications

If the patient develops an early reaction of significance, such as hypotension or bronchospasm, the clinician should halt the antivenom infusion, treat the reaction, then cautiously restart the antivenom infusion, if necessary titrating the antivenom rate against the epinephrine rate (if using an IV epinephrine infusion, via a pump), to maintain blood pressure (Grade III recommendation) [1, 4, 5, 19, 35]. After a short while, it may be possible to reduce the epinephrine rate, as any reaction subsides. Antivenom therapy should not be abandoned just because the patient has an adverse reaction.

The major delayed reaction to antivenom is serum sickness [4, 5]. Although unproven by clinical trial, it often is recommended that patients receive a 5–7-day course of prophylactic oral steroids to reduce the incidence of serum sickness [4]. This complication may increase in rate with increased volumes of antivenom [4, 5], though some studies have questioned this [50]; any patient receiving greater than 25 mL of antivenom probably should be considered for a course of prophylactic steroids [4].

Criteria for ICU Discharge in Australian and Pacific Snake Envenoming

Evidence of resolution of significant effects of envenoming (coagulopathy, myolysis, flaccid paralysis, renal failure) to the point that major risk is no longer present.

In cases of suspected snakebite that develop no evidence of systemic envenoming, 12–24 h post bite.

Other Treatments

Even though tetanus rarely occurs after snakebite, it remains a risk and tetanus immune status should be reviewed (Grade III recommendation) [4]. No injection should be given, however, until venom-induced coagulopathy is fully resolved [4]. Routine antibiotic therapy is inappropriate because bite wound infections are uncommon [4]. For patients with mostly postsynaptic paralysis (e.g., most death adder bites), neostigmine may be a useful adjunct to antivenom therapy [4].

Special Populations

Pediatric Patients

Young children, owing to their smaller size, are at greater risk of severe envenoming and so require even greater vigilance. Antivenom dosage is the same as for adults. Intravenous fluid therapy needs to be monitored carefully to prevent overload.

Pregnant Patients

There are few records of snakebite in pregnancy, and it is unclear which, if any, venom components might cross the placenta. Antivenom poses far less risk than envenoming in pregnancy, and there should be no reluctance to start antivenom treatment. Where practical, fetal well-being should be monitored.

Elderly Patients

The elderly are more likely to die as a result of major envenoming because they are at greater risk of secondary problems, such as renal damage and fluid overload.

Other Special Populations

The most important special population is the amateur and professional herpetologist community, whose members are at risk of repeated bites, with potential for severe allergy to antivenom and venom [4]. Venom may cause lethal anaphylaxis within minutes of the bite, long before hospital care can be accessed. Because of the potential to develop major allergies to antivenom, its use in herpetologists should be slightly more conservative than in the general population, but even so, antivenom should never be withheld when clearly indicated.

Common Misconceptions about Australian and Pacific Snake Envenoming

1. All snakebites require antivenom therapy.
2. A positive Snake Venom Detection Kit result indicates antivenom therapy is required.
3. Coagulation factor replacement is required to treat coagulopathy.
4. Antivenom is more dangerous than envenoming.
5. Intensive care unit (ICU) management of airway and respiratory function is sufficient to keep the patient alive, and antivenom is unnecessary.
6. ICU specialists can manage snakebite alone, as with other emergencies.

Key Points in Australian and Pacific Snake Envenomation

1. Most Australian snakebites ultimately prove to be minor, or “dry” bites, not requiring antivenom therapy.

2. Most New Guinea snakebites are major, requiring antivenom therapy.
3. Diagnosis is based on presence of specific systemic effects (as above), determined by examination and appropriate laboratory tests.
4. A positive Snake Venom Detection Kit on either bite site or urine indicates only that venom has been detected and the type of snake that has bitten. The requirement for antivenom is based on clinical and laboratory evidence of significant systemic envenoming.
5. Antivenom is the most important treatment. It should always be given intravenously. Always be prepared to treat an anaphylactic adverse reaction.
6. If there is major presynaptic paralysis with established airway or respiratory compromise, antivenom is unlikely to reverse this, and ICU skills are essential, but the effects of coagulopathy, myolysis, and secondary renal failure are the major causes of snakebite fatalities, and at least for the first two, antivenom is the cornerstone of treatment.
7. Antivenom (correct type in sufficient quantity) effectively abolishes general symptoms, may reverse at least some types of coagulopathy, may reduce myolysis, can reverse predominantly postsynaptic paralysis (e.g., death adders), but cannot reverse established severe presynaptic paralysis.
8. The type of envenoming and the most appropriate antivenom and initial dose requirements are largely determined by the type of snake; identifying the snake using venom detection plus diagnostic algorithms is important.
9. The clinically important effects of snakebite in Australia and New Guinea are systemic, not local: flaccid paralysis, defibrination or anticoagulant coagulopathy, myolysis, and renal damage.

(continued)

10. The extent of envenoming is not reflected in the local bite site reaction, which may be trivial despite life-threatening envenoming.
11. Snakebite is a potentially complicated illness that is seen infrequently in most ICUs. It is always sensible to seek outside expert assistance in managing snakebite, particularly if there is severe envenoming.
12. Coagulopathy of the consumptive variety (defibrination) may be reversible with antivenom therapy or by waiting for all venom to be cleared (the latter option prolongs the risk of lethal hemorrhage); use of coagulation factor replacement therapy (fresh frozen plasma, cryoprecipitate, whole blood) while procoagulant is still circulating merely “adds fuel to the fire,” making matters worse, not better and heparin has not been demonstrated as being beneficial.
13. Antivenom is *not* more dangerous than envenoming. Several people die each year from snakebite envenoming, many more in New Guinea, but deaths from adverse reactions to antivenom are rare and generally occur when no provision has been made to treat anaphylactoid reactions.

References	2451

Snakebites are a major public health problem in a number of African, Asian, and Latin American countries, and thousands of deaths are reported every year [1]. By comparison, this risk of venomous snakebite is much lower in Europe, where native species are less dangerous and the number of snakebite cases is low. Recent epidemiologic studies [1, 2] based on a meta-analysis of medical literature showed that with a population of 750 million inhabitants, Europe (including European regions of Turkey and Russia up to the Caucasus and Ural Mountains) records 7500 cases of snakebite per year. Approximately 1000 of these bites are associated with signs of severe envenomation requiring prolonged hospitalization. Fewer than five deaths are recorded every year in the old continent. In spite of these reassuring findings, several recent studies have been carried out in Europe and have allowed development of specific treatments and protocols for management of envenomed victims [3, 4].

European Vipers

Zoology and Distribution

Apart from a few toxicologically less important non-front-fanged *colubrid* species (see special paragraph), all naturally occurring venomous snakes in Europe are so-called vipers (family Viperidae, subfamily Viperinae, mainly genus *Vipera*; but species of the genus *Macrovipera*

and the genus *Montivipera* are also naturally present in continental Greece, Cyclades Archipelago, and European Turkey) [1].

Several species of the *Vipera* genus living in Europe are considered harmless to humans, i.e., the Basque viper (*Vipera seoanei*) and the meadow viper (*Vipera ursinii*) have never been implicated in serious envenomation [5, 6]. Both are small snakes living within a limited area and are not medically significant. Other smaller-sized species like the snub-nosed viper (*Vipera latastei*) in Spain are able to induce moderate envenoming with local symptoms, mild systemic symptoms, and, very rarely, severe or lethal envenoming [7]. Three species are larger snakes that range from 40 to 60 cm in length and can be the origin of envenomations with possible and frequent life-threatening situations, i.e., the adder (*Vipera berus*), the asp viper (*Vipera aspis*), and the long-nosed viper (*Vipera ammodytes*) [3].

Vipera berus is adapted to cold regions and can be found in Scandinavian countries beyond the Arctic polar circle. The common European adder occupies more land area than any other venomous snake. It occurs throughout Europe except for

Ireland, the southern parts of the continent, and the larger Mediterranean islands. Its range extends eastward through Asia to the Pacific Ocean. Northern France and the mountainous regions of central France mark the southernmost extension of the habitat of this species that is common in Sweden and England (Fig. 1).

Vipera aspis, which requires sun and warm temperatures, is mostly found in northern Spain, Switzerland, Italy, and France where it can proliferate in suitable environments. Pattern markings are highly variable, even within the same population (Fig. 2).

The larger *Vipera ammodytes* is widespread in Southeastern Europe, Northern Italy, Austria, and Turkey. All of these snakes are divided into subspecies in certain areas, and variations of clinical toxicities are seen (Figs. 3 and 4).

Circumstances

Bites generally occur outdoors when people incidentally come across the snakes in their natural habitat. Also, careless handling of snakes by

Fig. 4 Adult *V. ammodytes* (Courtesy of, and copyrighted by, Julian White)

private collectors may result in bites and envenomation. Bites mostly strike the extremities but also may impact the trunk, neck, and head (e.g., during swimming or when lying on the ground). *V. latastei* may stay in trees, which explains the occurrence of bites to the head and trunk in farmers harvesting fruits.

Venom

Composition and Pathophysiology

Although the European vipers differ in appearance and size, they are closely related in terms of venom composition and clinical effects of envenomation [3, 8]. The main components of the venom are proteins with enzymatic and toxic properties, such as hyaluronidase, proteolytic enzymes, peptide hydrolases, phospholipases A₂, and phosphodiesterases. Amino acids, polypeptides, carbohydrates, and metalloproteins are also present in the venoms.

The onset of venom enzyme activity is more or less immediate. Subcutaneous tissues, muscles, capillary endothelium, and basement membranes are damaged, with subsequent extravasation of plasma and erythrocytes, leading to progressive tissue swelling and discoloration of the skin. This process may not peak for 72 h after the bite.

A wide range of systemic effects is initiated through the activity of venom enzymes. Common acute effects, such as hypotension, gastrointestinal upset, angioedema, and bronchospasm, are due to an enzyme-mediated release of potent endogenous substances, such as histamine, bradykinin, prostaglandins, and serotonin. Local and systemic hemolysis and coagulopathies can be induced by venom enzymes.

The venom likely also contains components with more specific toxic properties. This explains the cranial and peripheral nerve disorders observed after bites by several populations of *V. ammodytes*, *V. aspis*, and *V. berus* suggesting neurotoxic components [9–11]. Similarly the early occurrence of hematuria and proteinuria in some populations of *V. berus* envenomation [12] indicates a specific nephrotoxicity. The presence of a cardiotoxic ingredient cannot be ruled out either, with numerous reports of electrocardiogram changes observed after bites by European vipers [12].

Toxicokinetics

Venom normally is injected intracutaneously or subcutaneously. Bites by the larger-fanged species (*V. ammodytes*, *V. aspis*, and *V. berus*) occasionally may result in intramuscular deposition of the venom and, in rare instances, intravenous injection.

Venom has been detected in blood 30 min after the bite and with a peak concentration observed at approximately 2 h [13]. Plasma venom concentrations decline slowly over 1–2 days, but venom has been detected up to 1 week after the bite [12].

Venom spreads rapidly in the local tissues, where its distribution is facilitated through the action of hyaluronidase. The venom is transported further to the systemic circulation through the lymphatic system. This transport is enhanced by simultaneous muscular activity, making immobilization and rest important first-aid measures.

Clinical Presentation

Severity

The severity of envenomation varies. Anything from just fang marks – with no signs of envenomation – to severe systemic reactions and extensive swelling is possible. The larger species in Southern and Southeastern Europe are often claimed to cause more pronounced symptoms, but this is not confirmed convincingly in existing reports.

The great variation in toxic response to bites is related to several factors. The most important is the *dose of injected venom*. Of snakebites, 30–50% are considered to be “dry,” meaning no injection of venom; this has led to the misconception that the venom is not dangerous. The *age and weight* of the patient are also crucial, explaining why small children are especially susceptible. Other important factors for the response are the *location of the bite* (bites on the head and neck could pose higher risk), *previous health state*, and *physical activity* after the bite. There are two reports of cardiovascular collapse following strong physical activity directly after a viper bite [3, 14].

Clinical Features and Gradation

Since the beginning of the 1990s, a European grading scale based on clinical features (Table 1) has been validated for evaluation of viper envenomation [8, 15]. The utility of this scale has been confirmed in several clinical series [4, 14, 16, 17], and it is now used in several European countries [1–3].

Vipers inject venom under pressure with the bite lasting only a few tenths of a second. In some cases there may be only one fang mark. When there are two punctures, the distance between them may be a few millimeters initially but then increase to over 1 cm as swelling develops. In grade 0, pain is moderate and limited to the injection site due to fang puncture. If symptoms do not progress with time, it is safe to assume that no venom was injected (grade 0).

Table 1 Clinical gradation table of envenoming by European vipers

Grade 0 = no envenomation or “dry bite”
Fang marks
No swelling
Grade 1 = minimal envenomation
Local swelling around the site of bite
No systemic symptoms
Grade 2 = moderate envenomation
2a with regional swelling (most of the bitten limb) and/or hematoma, adenopathy
2b = 2a + moderate general clinical effects such as mild hypotension, vomiting, diarrhea, neurotoxic symptoms, and/or biological criteria for severity (thrombocytes < 150G/L, leukocytes > 15G/L, INR > 1.5, fibrinogen < 2 g/L)
Grade 3 = severe envenomation
Extensive swelling spreading to the trunk and/or severe general symptoms (Table 2)

The hallmark of grade 1 envenomation is immediate severe pain, likely due to proteases, biogenic amines, and other venom components. Pain is followed within a few minutes by inflammatory edema and sometimes blistering at the bite site. Most envenomings stabilize at grade 1 and then regress spontaneously within 24–72 h.

Grade 2 envenomations are observed in only 15–20% of viper bite cases in Europe, though the percentage varies from place to place depending on the snake populations. Grade 2 symptoms can develop either rapidly (early grade 2) with the appearance of low blood pressure in the first 30 min after the bite or over a period of 6–16 h (classic grade 2) with extensive swelling and sometimes general symptoms (vomiting, abdominal pain, and malaise). Systemic manifestations such as diarrhea or arterial hypotension not resolved with fluid or colloid resuscitation are unfavorable prognostic signs. For grade 2, laboratory findings may show asymptomatic hemostatic disturbances (Fig. 5).

Grade 3 envenomation is defined as grade 2 effects lasting for several hours with development of extensive swelling of the trunk due to the absence of specific treatment (Fig. 6). Persistent general clinical manifestations are associated with

Fig. 5 The first captured neurotoxic specimen of *Vipera aspis aspis* in Southern France in 1991 (Photography of the Marseilles' Poison Centre)

Fig. 6 Typical locoregional aspect of a grade 3 envenomation by *Vipera aspis* in Western France with a giant blistering with blood and swelling plus hematoma of the trunk of a young envenomed girl (Photography of the Angers' Poison Centre)

numerous complications that can lead to multiple organ failure, e.g., renal insufficiency due to tubulopathy or glomerular nephropathy and hypoxia with variable bleeding due to pulmonary lesions related to edema, occasionally with pleural effusion, multiple episodes of digestive or respiratory bleeding, etc. Laboratory tests in grade 3 envenomings often reveal severe abnormalities including thrombocytopenia, hyperleukocytosis, and hypofibrinogenemia, severe water-electrolyte imbalance, or coagulation disturbances.

Serologic studies in viper bite victims confirm a close link between blood concentration of venom and severity of envenomation. The use of ELISA to measure venom blood levels has been shown to predict short-term clinical course [15, 17]. However, this technique is still experimental and is not yet adapted to emergency situations.

Some populations of the three dangerous European vipers have neurotoxins that cause special clinical manifestations characterized by low-grade local or regional effects immediately after venom injection and appearance of general

neurologic signs within 4–12 h [9, 10, 18]. The most frequent effect is ptosis, but other signs have been reported including ophthalmoplegia, diplopia, dysarthria, paralysis of the orbicularis oris, and difficulty in swallowing and focusing. In some cases, more extensive neurological manifestations with drowsiness, vertigo, dyspnea, and diffuse paresthesia have been observed [10, 14, 19]. This unusual envenomation pattern has been described not only in a small area of Southern France [10] and Italy [19–21] with asp vipers but also in Hungary [22, 23] and Bulgaria [24] with adders and in the Balkans with the long-nosed viper.

The grading system used for typical envenomation (Table 1) is also applicable to viper envenoming involving neurotoxins (Table 2) [3, 10]. Neurologic manifestations should be considered as general signs and are associated with grade 2. A recent study described a case of proven Guillain-Barré syndrome after a *Vipera aspis aspis* bite. The asp viper came from the southern French Alps and had no neurotoxins in its venom

Table 2 Indications for antivenom in bites by European vipers

Grade 2 or grade 3 envenomation with extensive swelling. General symptoms as potential evidence of venom diffusion must always be considered as an indication for antivenom infusion:
Circulatory instability that responds poorly to symptomatic treatment or recurs
Protracted or recurring gastrointestinal symptoms
Mucous membrane swelling with the risk of airway obstruction
Diarrhea
Fluctuating level of consciousness, peripheral or cranial nerve paresis
In “borderline” cases, one or more of the following may support the indication:
Leukocytosis $>15\text{--}20 \times 10^9/\text{L}$
Metabolic acidosis
Hemolysis
Coagulation disturbances
ECG changes
Persistent severe pain

[25]. The neurological clinical feature was the consequence of an autoimmune reaction (cross-reaction between GM2 ganglioside and glycosidic epitopes of the concerned asp viper venom) of the patient who was not treated with specific antivenom despite suffering grade 2 envenomation.

Diagnosis

Diagnosis relies on confirming the bite and assessing the severity. In most cases, the diagnosis is obvious from the actual circumstances. One to four fang punctures may be observed.

In many European regions, there is just one naturally occurring viper species. Even if more than one indigenous species is present in a certain region, a precise identification is seldom necessary. The different vipers in Europe are closely enough related to respond to the same treatment – including antivenom. There seems to be an acceptable amount of cross-reactivity for most species.

Severity is categorized by careful assessment of the clinical evolution of the bite. Early signs of

severe envenomation are hypotension, impaired consciousness, intense or long-lasting gastrointestinal symptoms, respiratory distress, and rapid progression of local swelling. The degree of pain does not correlate with the severity of the bite. Leukocytosis greater than $15\text{--}20 \times 10^9/\text{L}$, pronounced hemoconcentration, metabolic acidosis, hemolysis, and coagulation disturbances similarly indicate high venom dose and a risk of further serious effects.

Based on ELISA results for detection of venom, there is evidence for a good correlation between clinical signs and the blood concentrations of venom antigen in patients bitten by *V. aspis* and *V. berus* [8, 13]. This correlation has been confirmed further in a study of patients envenomed by *V. aspis* and *V. berus* [6, 17]. In the average clinical setting, clinical evolution, rather than venom antigen levels, provides treatment guidance.

Treatment

Medical management of viper envenomation must follow strict rules [3, 14].

What to do at the bite scene (first aid): Immobilize the bite site and stay as quiet as possible to keep venom from spreading. Call for assistance as quickly as possible. If the bite takes place in a remote area and it is necessary to seek a means of communication, the victim can be carried (e.g., children) or left at the scene (preferably with another person). Provide rescuers precise details about the location of the patient. While waiting for assistance, remove tight clothing and jewelry (watches, bracelets, rings, etc) before swelling starts and, if possible, disinfect the wound.

What not to do at the bite scene: Do not restrict circulation by applying tight bands or tourniquets. Do not promote spreading by giving drinks that increase heart rate (coffee or tea). Do not perform mutilating acts such as wound incision, suctioning, or cauterization. Do not give alcoholic beverages or recreational drugs. Do not administer antivenom without medical supervision.

What to do during transportation to the hospital: The presence of any local manifestations indicates grade 1 envenomation and requires hospitalization. Placement of an intravenous line is a necessary precaution to allow immediate treatment of arterial hypotension. Nonsedating analgesics such as paracetamol should be administered in cases of severe pain.

What is not useful during transportation to the hospital: Administration of heparin or its derivatives is unnecessary and unhelpful. Injection of low-molecular weight heparin may promote spreading of venom. Administration of corticosteroids is also unnecessary. Aspiration devices, e.g., pumps, cannot extract venom injected deep within tissue and are not recommended.

At the hospital: Prompt clinical assessment with interview, examination, and grading is necessary upon arrival at the hospital (Table 1) [17]. Thorough laboratory testing should also be carried out including hemogram, hemostasis (platelets, prothrombin time, INR, aPTT, fibrinogen, and fibrin degradation products), and kidney functional testing (creatinine, urea, plus testing urine for hematuria, proteinuria).

For patients with grade 0 envenomation: A 4-h surveillance period in the emergency room may be proposed. However, the need for surveillance is controversial since the absence of pain rules out injection of venom and makes progression of symptoms unlikely.

For patients with grade 1 envenomation: hospitalization is required for at least 24 h since venom has been injected and outcome is unpredictable. The bitten extremity should be immobilized in an elevated position and appropriate supportive treatment should be administered including analgesics, such as paracetamol, or on the hospital, if necessary, opioids. Antibiotics should be administered only if bacterial infection is suspected. In this regard, oozing of purulent material from puncture sites is a common early indicator of contamination.

For patients with grade 2 or 3 envenomation: intravenous immunotherapy with antivenom must be undertaken. Several antivenoms are available, but some are preferentially used in certain countries.

Viperfav*

Viperfav* is the current antivenom used in France and Italy. It contains equine F(ab')₂ fragments obtained from antibodies produced in response to venoms from *Vipera berus*, *Vipera aspis*, and *Vipera ammodytes* (500LD₅₀, 1000LD₅₀, and 1000LD₅₀, respectively, per 4 mL bottle). Viperfav* has been approved for marketing and use only in a hospital setting. The required dose of antivenom depends less on the victim than on clinical features related to the quantity and quality of the venom which are linked to the snake's physiologic state and on the circumstances under which the bite occurs. The dose of antidote is the same in children and adults, but the volume of saline used to dilute the antivenom is adapted to patient weight.

Approval of Viperfav* in France was obtained based on studies showing good tolerance [16] and excellent effectiveness [17] in envenomed patients. Since it contains heterologous proteins, it must be administered under medical supervision. Preventing life-threatening effects of envenomation outweighs the risk of anaphylactic reaction that is usually manageable in a properly equipped hospital setting. Thanks to techniques now available for purification of antivenom, as well as to current levels of viral security, recent products like Viperfav* are considered as safe medicines. Toxicokinetic studies have shown that the intravenous route provides prompt neutralization of venom antigens in the bloodstream and tissue and is now the only recommended route [3, 13].

European Viper Venom Antiserum (Serum Antiviperinum)

European viper venom antiserum (serum antiviperinum) is made from purified equine F(ab')₂ fragments (Institute of Immunology, Zagreb, Croatia). The typical dose is one vial (10 mL) diluted in 200 mL of physiologic saline and given as an infusion over 60 min. The same dose is given to adults and children, though the total volume of the infusion may be adjusted. Additional doses may be required depending on the clinical course.

ViperaTab

ViperaTab is made from affinity-purified ovine Fab fragments (Protherics Ltd., London, UK). The typical dose is 200 mg (the contents of two ampuls) dissolved in 10 mL of sterile water (two ampuls of 5 mL), then diluted in 100 mL of physiologic saline, and given as an infusion over 30 min. The same dose is given to adults and children. Additional doses may be required depending on the clinical course [26]. A recent article suggests that this antivenom may be a valuable therapeutic antidote for treating snakebite by a variety of European vipers found throughout the continent [27].

Neurotoxins: Phospholipase A₂ neurotoxins in the venom of some French asp vipers are similar to vipoxin and ammodytoxins of *Vipera ammodytes* [10, 11]. *Vipera ammodytes* venom is used to immunize horses for production of Viperfav*. Antibodies against *Vipera ammodytes* neurotoxins are effective in treating neurotoxic symptoms induced by asp vipers in Southern France and Northern Italy [3, 10]. For this reason Viperfav* is recommended for neurotoxic envenomation (level of evidence II-3) with recent discussions concerning possible changes in antidote dosage [28].

Other treatments: Infection after snakebite is a non-negligible risk regardless of toxic manifestations. However, the need for systemic antibacterial therapy in Europe remains controversial. Unlike many tropical countries, infection after snakebite is uncommon in Europe. Close monitoring of the wound site is necessary to ensure prompt treatment if necessary. Tetanus has never been observed following snakebite in Europe, but immunization status should be checked and, if necessary, updated, preferably after any coagulopathy has substantially resolved.

Anticoagulant treatment using heparin or low-molecular weight derivatives provides no direct benefit for initial management of envenomation. A recent study in Western France showed that anticoagulant treatments are associated with longer duration of hospitalization for envenomed patients [4]. However, two indications may warrant its use. The first is to prevent possible venous

thrombosis in snakebite victims requiring prolonged decubitus due to extensive edema in the lower extremities.

The role of surgery is also limited and controversial. In the past, fasciotomy was recommended to relieve pressure and avoid peripheral compressive ischemia in cases of extensive edema. Current experience shows that immunotherapy using antivenom leads to prompt reduction in edema. Peripheral ischemia has not been reported in any recent European series describing viper envenomation treated with or without antivenom immunotherapy. Thus, fasciotomy is generally considered unnecessary for viper envenomation in Europe [3, 14] but is still used in rare cases after bites by species of the genus *Crotalus* in which elevated compartment pressures are documented and not relieved by appropriate antivenom therapy [29].

Criteria for ICU Discharge in Envenomation by European Snakes

Vital functions stabilized

Signs of ongoing systemic envenomation ceased

Local swelling not progressing

Further antivenom treatment not anticipated

Special Populations

Pediatric Patients

Small children constitute a special risk group and are overrepresented in hospital populations. All children who have been bitten by a viper should be observed for at least 24 h. The threshold for giving small children antivenom should be lower than in adults.

Pregnant Patients

Few data are available on snakebites in pregnancy, which might indicate that snakebite does not represent a particular risk to pregnancy. However, intrauterine death of the fetus has occurred in late pregnancy in two women after *V. berus* bites

(Swedish Poisons Information Centre, unpublished data). In both cases, there was significant envenomation with systemic and local effects. It seems logical to recommend prompt antivenom therapy for pregnant women to neutralize possible toxic effects of circulating venom on the placenta and fetus when signs of systemic envenomation are present.

Elderly Patients

Elderly patients may be more vulnerable, especially if they have cardiovascular disease.

Common Misconceptions about Envenomation by European Snakes

1. Viper venom is only moderately toxic because some people do not react at all.
2. Onset of severe symptoms is always early and rapid.
3. Corticosteroids have a neutralizing effect on the venom.
4. Antivenom treatment is more dangerous than the bite itself.
5. Antivenom has no effect on the local reactions.

Key Points in Envenomation by European Snakes

1. Immobilization and rest are essential.
2. Continuous observation is mandatory.
3. Life-threatening signs (circulatory shock, airway obstruction) may appear abruptly.
4. Onset of serious signs symptoms may be delayed up to 24 h after the bite.
5. Symptomatic and supportive care should be started immediately and given as required.
6. Indications for antivenom treatment must be considered carefully.
7. Antivenom should be given early for optimal efficacy.

European Non-front-fanged Colubrids

There are numerous non-front-fanged colubrid species in Europe. The only one currently considered as venomous is the Montpellier snake (*Malpolon monspessulanus*), which lives on the French Mediterranean coastline, most parts of the Iberian Peninsula, and the Maghreb. It is the largest snake in the continent, growing up to 2 m long. The neurotoxic venom has not been extensively studied, but is powerful enough to rapidly paralyze prey. However, the snake cannot normally inject venom into humans because its fangs are located toward the back of the mouth and cannot easily be brought into contact with the skin. Most cases of human envenomation involving the Montpellier snake have occurred under special circumstances. A few cases have been reported in Spain and one case from Southern France was published [30]. In at least some cases, the bite victim had introduced his/her finger into the snake's mouth so that it was able to chew the skin and inject venom. It should be noted that of more than 70 reported cases of Montpellier snake-bite, accurate identification of the snake can only be assured in a very few instances. The main clinical manifestations are local reaction at the injection site (moderate pain and limited edema) that disappears within 1–2 h. Cranial nerve disturbance can occur 2–6 h after injection including ptosis, ophthalmoplegia, swallowing difficulty, speech impairment, and accommodative dysfunction. These symptoms can be associated with extreme weakness and drowsiness, though full respiratory paralysis has not been reported. Bites by these snakes have been recently reviewed. [31]. No specific treatment exists. As colubrid venom is completely different than viper venom, antivenom for viper bites is ineffective. Care is provided, including analgesics and antibiotics, if necessary. Neurotoxic signs can last for 2–6 days.

Although all other colubrid species in Europe are fangless [32], this feature does not exclude the possibility that their saliva is venomous as the Duvernoy's glands can produce toxins even

though there is no physical venom apparatus [33]. In this regard, clear-cut differences have not been established in ophidians between venom and saliva. One case of envenomation by the green and yellow colubrid (*Coluber viridiflavus*) that has only conventional teeth was reported in a drunken man who wrapped the animal around his neck and was bitten repeatedly [34]. The circumstances of this case are exceptional, and a single colubrid bite is usually considered harmless, requiring only wound disinfection. It is noteworthy that colubrids are much more active than vipers and may bite more often.

“Colubrid” Snakes and the Functional Morphology of “Rear-Fanged” Snakes

The world’s living snake fauna consists of approximately 3580 species, and the majority belongs to the superfamily Colubroidea, the “advanced snakes” (e.g., those with derived anatomical traits), that evolved during the Oligocene-Miocene periods of the Cenozoic Era. It should be noted that some authors utilize a more segregated but complex phylogeny in which the advanced snakes are all included in the infraorder Caenophidia with the families Elapidae and Lamprophiidae as part of the superfamily Elapoidea. The recognition of up to 11 inclusive families in this phylogeny is dependent on a given author’s cladistics interpretation. Therefore, although the Colubroidea is used here for convenience, it should be noted that the dynamic nature of squamate reptile taxonomy might alter the usage/taxonomic accuracy of this particular phylogeny.

Approximately 700 colubroid snake species (roughly some 19.5%) are front-fanged (front-fanged colubroids, FFC) and possess either relatively “fixed” (family Elapidae) or distensible front fangs (family Viperidae and two genera of the family Lamprophiidae) in the maxilla that have variable morphology, but all have an enclosed lumen (canal) and orifice, which superficially resemble a hypodermic needle (Fig. 1). In general, elapid fangs may be considered “fixed,” meaning relatively immobile and in a permanently erected position in the maxilla; there are a number of species (e.g., Australian coastal taipan, *Oxyuranus scutellatus*) that have significant fang mobility. The term “fixed” is primarily used in order to grossly distinguish elapid fangs, which are frequently called “proteroglyphous,” from the generally more mobile fangs, often termed, “solenoglyphous,” of viperids and atractaspidine lamprophiids. The variability and embryological origins of ophidian dentition in the posterior maxillae renders the firm categorization of “fangs” as somewhat artificial, and the terminology is largely used for general convenience because it lacks precise accuracy.

The medical risks of many species of FFC have been formally recognized for several centuries, and envenoming inflicted by numerous clinically important taxa has been documented with increasing medical accuracy since the late nineteenth century. Of the extant FFC belonging to the families Viperidae (Old World vipers, subfamily Viperinae, and New and Old World pit vipers, subfamily Crotalinae) and Elapidae (cobras, mambas, coral snakes, sea snakes, and their allies), probably about 50% (some 300–350 species) are known to inflict medically significant bites on humans [1].

In addition, as noted above, two unusual genera (*Atractaspis* spp. [mole vipers, burrowing asps, or stiletto snakes, arguably about 21 species] and *Homoroselaps* spp. [African dwarf garter or harlequin snakes, 2 species]) of the primarily African family Lamprophiidae, subfamily Atractaspidinae (on occasion contracted to Atractaspinae), also have evolved front fangs, and those of *Atractaspis* spp. have notable mobility. Therefore, 55/57 genera and 286/309 species of the Lamprophiidae are non-front-fanged, and this may suggest that the front-fanged state arose in these two genera of robustly closely allied African snakes, independent to the evolutionary process that selected the front-fanged state in elapids and viperids. Although their medical importance has often been incorrectly underestimated, several *Atractaspis* spp. are medically important in sub-Saharan Africa and the Middle East, but there are also a number of lesser-known front-fanged species (including the aforementioned *Homoroselaps* spp.) of uncertain medical significance. This is partly due to the infrequent contact of these species with humans (e.g., many of these snakes are fossorial and/or are found in ecosystems in which contact with humans is rare), as well as the common lack of formal medical review of bites that may occur in isolated locales among remote human populations [1].

In reality, a relative handful of FFC species are responsible for most of the global annual snakebite-related human mortality and morbidity, which has been roughly approximated to include 45,000 – >100,000 deaths [8, 9]. This figure is

Fig. 1 Comparison of the venom delivery systems in a representative front-fanged colubroid (FFC) and a non-front-fanged colubroid (NFFC). (a) In the NFFC, the Duvernoy's gland (DG) or, "low-pressure venom gland", Duvernoy's venom gland, indicated by cross-hatching) is located in the temporal region. Although adjacent striated muscles are medially proximal to the gland fundus, they typically do not attach directly to it. (b) An enlarged cross-sectional view of the DG that depicts the internal duct system, which drains the relatively dense parenchyma. A single duct departing from a small central cistern delivers the newly synthesized contents to a cuff of buccal mucosa that surrounds the posterior or mid-maxillary tooth. (c) Infliction of a wound in the integument of the prey by the maxillary tooth shown in (b) causes the mucosal cuff to remain on the surface while receiving the gland secretion (venom) that flows around the tooth that may or may not be grooved. This is an open, low-pressure system. (d) The venom gland (*shaded*) of this FFC (most closely resembling that of a "proteroglyphous" species, e.g., an elapid) includes the main venom gland with a main duct, an accessory gland (that mainly secretes mucosal secretions), and a secondary duct that empties into the base of the

canaliculated, or hollow, fang. Striated muscle fibers insert directly onto the venom gland fundus thereby raising the intraglandular pressure and send a bolus of stored venom from the gland to the canaliculated fang. (e) A sagittal view of the venom gland showing the secretory epithelium and extensive storage reservoir of the gland. The typical DG has no comparable extent of storage volume. (f) When the canaliculated fang penetrates the integument of the prey, or unfortunate human, the attachment of the venom duct to the fang maintains the relatively high pressure head, and venom passes unobstructed through the lumen of the fang and is delivered deeply into the integument. Abbreviations: *adductor mandibulae externus superficialis* (AS), *compressor gloandulae* (Cg); accessory venom gland (Av), central cistern (Cc), common lobular duct (Cld), prey integument (Ep), fang/maxillary tooth (F), lobular duct (LD), lumen with secretory product (Lu), main duct (Md), maxillary bone (Mx), oral epithelium/buccal mucosa (Oe), buccal mucosal cuff around tooth (Pk), primary venom duct (Pd), secondary venom duct (Sd), secretory epithelium (Se), main venom gland (Vg) (After Weinstein and Kardong [9], used with permission)

probably an underestimate, and these envenoming also result in an inestimable number of significant chronic injuries that adversely affect the victims' activities of daily living. Several examples of

these most medically important FFC species include *Echis* spp. (the saw-scaled, or carpet, vipers, Viperidae, Viperinae), *Naja naja* and *N. kaouthia* (respectively, the common Asian

cobra and the monocled, or monocellate, cobra, Elapidae), *Oxyuranus scutellatus canni* (Papuan taipan, Elapidae), *Bitis arietans* (the puff adder, Viperidae, Viperinae), Russell's viper (*Daboia russelii*, *D. siamensis*, Viperidae, Viperinae), *Bungarus* spp. (various species of kraits, Elapidae), and *Bothrops asper* and *B. atrox* (respectively, the terciopelo, and barba amarilla, or common lance head; both are occasionally called "fer-de-lance," Viperidae, Crotalinae). These species collectively account for a large proportion of the global human mortality and/or morbidity from snakebite.

As briefly mentioned earlier, all of the known FFC possess a canaliculated (hollow or lumenate) venom apparatus located on the anterior maxillae that is associated with a venom gland whose contents are ejected under high pressure by compression of the gland through contraction of skeletal muscle fibers inserted in the gland fundus. In general, the venom glands of most front-fanged species have a pre-stored bolus of venom that is produced by slowly cycling columnar cells present in the venom gland, which synthesize and secrete multiple classes of venom components (primarily polypeptides and peptides). The stored venom bolus is thereby available for immediate injection under pressure (Fig. 1).

The larger number of colubroid species are non-front-fanged species (non-front-fanged colubroids, NFFC). Historically, many NFFC were inaccurately grouped in an amorphous and thus somewhat artificial family, the Colubridae, a group first defined in 1758 by the Swedish natural historian and founder of systematic zoology/taxonomy, Carl Nilsson Linnaeus (Carl von Linné or Carolus Linnaeus; 1707–1778). The name, "Colubridae," is derived from the rather non-descript Latin, *coluber*, the general term for "snake" or "serpent." Under the previous definition of the Colubridae, about 65–70% of extant snake species (e.g., about 2,350 taxa) were included in this poorly defined family. On the basis of several morphological and/or molecular systematic investigations (some conflicting), the number and identities of previous subfamilies included under the Colubridae have been redefined. Several have been raised to full family status and some have

been rendered artificial, while others have been retained within the original family that now comprises an estimated 1,800 species (about 75% of the previous assemblage). Although the majority of these snakes are still in the family Colubridae, they are now collectively, and more accurately, termed NFFC. As currently defined, these snakes are represented by taxa with wide distribution, but geographically variable abundance in the Neotropics, North America, Mexico, Africa, Asia and Southeast Asia, the Indian subcontinent, New Guinea, Europe, and with the least representation in Australia [1].

A general accounting of the Colubridae and newly defined families that previously were included as "colubrids" includes a diverse assortment of widely distributed species (Table 1) [1]. Some of these snakes have often been called "rear-fanged," "opisthoglyphous," or "aglyphous," referring to their posterior or mid-maxillary dentition that may or may not be enlarged and/or quite variably modified with external grooves and/or lateral ridges, but are not hollow and thus lack a fully enclosed internal lumen or canal (Figs. 1 and 2) [1, 3, 10]. As mentioned earlier, the notably variable position of the modified teeth in the maxilla contradicts the accuracy of the popular term, "rear-fanged," because these teeth in some of these snakes are not located in the "rear" (posterior) of the maxilla.

In some NFFC species (the precise number is unclear), this dentition is associated with a gland that is often considered distinctive from that of FFC and has been variously called "Duvernoy's gland" [11–14], "low-pressure venom gland" [1, 3], or "Duvernoy's venom gland" [15]. However, some investigators do not distinguish this gland from the viperid and elapid venom gland and thus also simply call it a "venom gland" [16]. An unknown number of NFFC possess these glands that produce variably toxic secretions released under low pressure due usually to a general lack of any significant skeletal muscle fiber insertion in the gland fundus [11, 16–18]. The differing terminology for these glands has resulted from investigator interpretation of functional morphology and/or glandular roles or assignment of identity

Table 1 Overview of the superfamily Colubroidea¹ and their medical significance

(Commonly used familial name) ²	Subfamilies [Number of medically relevant NFFC species identified from evidence-based analysis ³]	Approximate number of total genera and species ⁴	Comments
Colubridae ("Typical" snakes; "harmless egg-laying snakes") Natricidae Dipsadidae Pseudoxenodontinae [IC]	Colubrinae [12], Grayiinae [IC], Calamariinae [IC] Sibynophiinae [IC] None [3] None [28] ⁵ None [IC]	250 [1,750]	Cases not included in the summarized tally here featured mild, transient local effects. Six taxa have caused life-threatening effects or fatalities (see text). There is a lack of any information about the possible medical risks posed by the potential bites of a number of species that are entering the commercial trade (e.g., bamboo snake, <i>Pseudoxenodon bambusicola</i> , Pseudoxenodontidae). Some taxa are very rarely encountered (e.g., the two taxa of <i>Scaphiodontophis</i> , Sibynophiinae, and many others), and, in numerous cases, there is no substantial/reliable clinical information about the effects of bites from a given species
Lamprophiidae (sometimes collectively called, "African nocturnal snakes," although a single species, <i>Psammophis indochinensis</i> , Psammophiinae, occurs in Southeast Asia), and others (e.g., <i>Malpolon</i> spp.) range into Europe	Aparallactinae [1] ⁶ Atractaspidinae [NA] ⁷ Lamprophiinae [IC] Prosymninae [IC] Psammophiinae [6] Pseudaspidinae [IC] Pseudoxyrhophiinae [5]	61 [300]	One species has inflicted a single well-documented case of systemic envenoming featuring cranial nerve palsies (see text). To date, most well-documented cases feature mild, transient local effects. However, bites from larger specimens of some species may be capable of producing more significant effects. Currently, there is no clinical information that supports common speculation of the hypothetically more serious effects of bites from large specimens of <i>Psammophis</i> spp. ("sand snakes," Psammophinae) Although envenoming cases are not included in the tally because they are front-fanged, all of the <i>Atractaspis</i> spp. must be considered medically important as their bites have caused fatalities, and some species are significant causes of snakebite within their respective ranges
Homalopsidae (Australasian mud snakes)	----- [IC]	11 [38]	Mostly anecdotal information; the few medically well-documented reports indicate mild, transient local effects. Larger specimens of some species may be capable of inflicting a bite with more significant local effects
Pareatidae (Asian slug-eating snakes)	----- [IC]	3 [15]	Ibid
Xenodermatidae ("strange-scaled snakes"; see comments)	----- [IC]	5 [17]	Rarely encountered and reportedly reluctant to bite, there is no available relevant clinical information. Several specimens of these unusual snakes were briefly maintained by the author, and none attempted to bite, but rarely handled due to their fragile nature
Viperidae (vipers and pit vipers)	Azemiopinae, Crotalinae Viperinae [NA]	39 [300]	The medically serious, life-threatening and/or fatal bites of a large number of species have been thoroughly documented. However, the medical risks of some species are unestablished due to their remote habitats, infrequent contact with human populations and/or lack of medically qualified documentation of their bites

(continued)

Table 1 (continued)

(Commonly used familial name) ²	Subfamilies [Number of medically relevant NFFC species identified from evidence-based analysis ³]	Approximate number of total genera and species ⁴	Comments
Elapidae (sometimes collectively called, “fixed-front-fanged snakes”; see comments)	Hydrophiinae ⁸ [NA]	65 [350]	Ibid There is very limited or a lack of information about the medical risks that may be posed by some small fossorial species (see the previous entry)

¹The taxonomy of the Colubroidea is fluid and under continuing review and reassignment. The taxonomy included here follows that of Pyron et al. [2]

²Traditionally used by some authors, these common names do not accurately encompass the diverse members of this large family because some are viviparous (some previously termed, ovoviviparous) and some are not “harmless,” or “typical” (see text)

³Based on the critical analysis of Weinstein et al. [3], and is limited to only those species for which available clinically relevant information is sufficient for risk assessment. This tally is limited to a summarized number of species that have inflicted bites that have included some clinically significant pathological effects, for example, ranging from some locally progressive but minor edema to bites with a fatal outcome. Bites resulting in simple puncture wounds and lacerations with reactive erythema are not included in the summarized figure. There are very likely a number of other NFFC that may have medical significance under some multifactorial circumstances

⁴This approximate number estimates the number of genera and species (in brackets) contained in the family listed

⁵This summarized number includes a single entry for some species such as the South American burrowing snakes, *Apostolepis* spp., a genus with some 26 taxa. The single number reflects the results of a collected series of reported bites that provide documentation of some significant uncomplicated local effects of bites from members of this genus without individual species identification

⁶The single taxa included here is the Natal black snake, *Macrelaps microlepidotus*, a monotype that is considered a provisional member of either the Atractaspidinae or the Aparallactinae, depending on author. Therefore, the taxonomic status of this species remains unconfirmed. Purely for the sake of the medically relevant discussion here, it is included with the Aparallactinae here in order to separate it from the front-fanged atractaspidines (see next footnote)

⁷This subfamily is provisionally recognized by some investigators, and not by others who still consider Atractaspididae as a full family. *Atractaspis* spp. and the other allied genus, *Homoroselaps* spp., grouped with *Atractaspis* spp. on robust morphological grounds, are the only front-fanged colubroids assigned to what otherwise is a NFFC clade. See Pyron and Burbrink [4], Vidal et al. [5, 6] and Zaher et al. [7] for detailed information about the problematic taxonomy of some of these assignments

⁸Most taxonomists no longer recognize this subfamily or several others that were previously proposed or used (e.g., Micrurinae, Laticaudinae, Elapinae, etc.). The Hydrophiinae is included only because it appears in some of the relevant literature

Figure after Weinstein et al. [1]; used with permission

Abbreviations: NFFC Non-front-fanged colubroid snakes, NA not applicable, IC insufficient information/lack of documented case reports

based primarily on phylogenetic relationships [1, 3].

Delivery of the oral product, venom, or other products with potential toxicity to the animal (including human) recipient is an important consideration when evaluating potential medical risks of a given ophidian species. Compressed high-pressure FFC venom glands release a bolus of stored venom and facilitate its injection into prey or a human victim. The pressure of injection may exceed 30 psi, which is similar to a typical automobile tire pressure [19]. In contrast, NFFC

inoculate their secretions under low pressure (the few studied species produce ≤ 5 psi [19]) into wounds produced by maxillary teeth that may be variably grooved. Those with surface grooves may have shallow grooves that in some species may resemble superficial indentations or may be deeply etched with a longitudinal groove that extends over almost the entire dentary surface. A small assortment of studied species have partially enclosed grooves, but these still remain part of a low pressure, open system [1]. The medically important colubrine colubrid, *Dispholidus typus*

Fig. 2 Posterior grooved (arrows), enlarged maxillary tooth of the brown tree snake, *Boiga irregularis* (Colubridae, Colubrinae) (Photo copyright to Scott A. Weinstein)

Fig. 3 Boomslang (*Dispholidus typus*, Colubridae, Colubrinae). This Hazard Index 1 species has medical importance in East Africa and South Africa. It has a wide gape, multiple, deeply grooved posterior maxillary teeth, and some limited striated muscle attachment on the venom gland fundus, which likely partially pressurizes the gland. This aids delivery of highly potent procoagulant venom that exerts its clinically important effects by a combination of prothrombin activation and rhexic hemorrhagic action of metalloproteases (Photo copyright to David Warrell)

(boomslang, Fig. 3), and possibly other members of the tribe, Dispholidini, as well as perhaps a few other unrelated taxa, have limited striated muscle insertion into the gland resulting in a partially pressurized venom delivery system [1, 3].

Fig. 4 At least two species of the African twig, bird, or vine snakes, *Thelotornis* spp. (Colubridae, Colubrinae), have inflicted fatal envenoming that is very similar to that caused by *Dispholidus typus*, as it features consumptive coagulopathy and hemorrhagic diathesis. Treatment of serious envenoming by any of these snakes is limited to replacement therapy and careful supportive management including hemodialysis in some patients with AKI. Pictured is the Eastern twig, vine, or bird snake, *T. mossambicanus* (Photo copyright to David A. Warrell)

However, even these species very likely generate significantly lower intraglandular pressures than that of NFFC and, also unlike medically important FFC, do not have appreciable capacity for a stored venom bolus. Nevertheless, this intraglandular pressure deficit does not preclude the risk of a medically significant envenoming from a quick bite and release delivered by *D. typus* and possibly other medically important dispholidines and natricids (see ahead).

Toxins and Other Components of NFFC Venoms and Other Oral Products

Modern snake venom research has spanned a relatively short period (approximately 80 year), and detailed investigations have largely focused on medically important FFC species. The venoms and other oral products of NFFC have received far less attention [1, 3]. Although early twentieth century South African researchers were aware of the human lethal potential of boomslangs (*Dispholidus typus*, Colubridae, Colubrinae), wider interest in the biomedical properties of the African dispholidines (*Dispholidus typus* and the African twig, bird, tree, or vine snakes, *Thelotornis* spp., Fig. 4) was stimulated by the tragic and publicized deaths of two distinguished herpetologists, Karl P. Schmidt (in 1956) and Robert F.W. Mertens (in 1976). Similarly, the

Fig. 5 Another Hazard Level 1 species, the tiger keelback, or Yamakagashi (*Rhabdophis tigrinus*, Natricidae), has caused multiple fatal envenoming in Japan. There is effective antivenom against this taxon, and it has been used successfully to treat life threatening envenoming by this species (Photo copyright to Dr. S. Mishima)

Fig. 6 The red necked keelback (*Rhabdophis subminiatus*, Natricidae) has inflicted serious coagulopathic envenoming, but unlike its congener, *R. tigrinus*, has not caused any human fatalities. So far no envenoming by this species has been treated with *R. tigrinus* antivenom, although it is likely to have clinically important paraspecific neutralizing capacity. This antivenom should be used in life-threatening envenoming by this species (Photo copyright to Taksa Vasaruchapong)

potentially fatal effects of tiger keelback or yamakagashi (*Rhabdophis tigrinus*, Natricidae, Fig. 5) envenoming were long known to some Japanese investigators, but the life-threatening bite from a privately owned red-necked keelback, *Rhabdophis subminiatus* (Fig. 6), in London in 1978 also sparked wider interest in the venoms of these species, as well as those of other NFFC that might have medical importance [3]. Contemporary biochemical and pharmacological investigations are greatly expanding knowledge of the Duvernoy's gland secretions and venoms of NFFC. However, advances in this subdiscipline are greatly hindered by an almost complete lack of active research funding and disinterest by relevant "mainstream" biomedical disciplines, as, aside from *D. typus*, there is limited demonstrable medical importance attributed to most NFFC [1, 3, 10].

Biochemistry

The composition of NFFC venoms and other oral secretions is similar to that of venoms of viperids, elapids, and *Atractaspis* spp. [1, 3] although some NFFC venoms/oral secretions are less complex than venoms of viperids and elapids (e.g., those

from the homolopsid, *Cerberus rynchops* [dog-faced water snake, Fig. 7] [20], and the dipsadid, Lichtenstein's green racer [*Philodryas olfersii*, Fig. 8] [21]). A handful of biologically active components present in the oral secretions/venoms and glands of NFFC have been characterized. Some of these belong to the known classes of snake venom components (Table 2). Recent proteomic, genomic, and transcriptomic investigations have identified some of the components detected during early chromatographic studies of NFFC venoms and secretions [1, 3] and/or have reported the presence of previously undetected classes of biologically active constituents including cysteine-rich secretory proteins, multiple enzymes and isozymes (e.g., metalloproteases, phospholipases A2, fibrinogenases, Factor X and prothrombin activators, and others), mycotoxins, as well as postsynaptic neurotoxins (see Table 2 for representative examples). To date, the few well-characterized neurotoxins [three-finger-fold toxins] have shown greater specificity for the saurian and/or avian motor end plate (Table 2).

Assessment of NFFC venom/other oral secretion biomedical activities should include essential consideration of their biological functions, as

Fig. 7 Although most studied venoms from NFFCs show complexity similar to that of FFCs, the venoms of some NFFC such as this Australasian homolopsid, the dog-faced watersnake, *Cerberus rynchops*, are less complex. The few documented bites by this species have featured only minor puncture wounds and mild reactive edema/erythema (Photo copyright to Eng Wah Teo)

Fig. 8 Lichtenstein's racer, *Philodryas olfersii* (Dipsadidae), is gaining recognition as a species with some occasional medical importance in South America (especially Brazil). This Hazard Index 2/3 species can occasionally inflict systemic envenoming so far characterized by widespread ecchymoses (see Figs. 27 and 28). Although there are anecdotal reports of coagulopathic envenoming from this species, to date there are no well-documented reports that establish consumptive coagulopathy after a bite from this species. There are also anecdotal reports of fatal envenomings, but these are unsubstantiated and unsupported. There is no antivenom that is effective for treating bites from these snakes, and serious envenoming is managed supportively with meticulous wound care (Photo copyright to Pedro H. Bernardo)

this can help the construction of a medical hazard profile for the species. Therefore, it should be noted that the majority of NFFC produce oral products have unknown biological properties and/or functions [1, 3, 22]. Consequently, one can view that many of these oral products are

“assumed” to be venom, as they are identified as such solely on the detection of classes of proteins/toxins that are described from elapid and/or viperid venom components and without quality evidence of their function, e.g., their possible role in the subjugation of prey, and/or the facilitation of prey capture, or role in self defense, as these are traditional roles used to define snake venoms [22]. Therefore, using a strict scientific standard, a relatively small number of these snakes can be considered to meet the traditional biological criteria defining them as “venomous,” although there is current debate concerning the definition of “venom” and the “venomous condition” [3, 22–25]. Snakes evolved venoms long before humans appeared on Earth, and the *most likely* primary impetus for their evolution was (and remains) prey capture/subjugation [1, 3, 22]. Therefore, it is important to recognize that the medical effects of snake venoms are a circumstantial result of the interaction of humans with snakes whose venoms or oral products coincidentally have a medically significant effect, and therefore these effects should not be used as criteria for defining snakes as “venomous” or not [1, 3, 17, 22, 26].

For the purposes of broad discussion of this large grouping of snakes, it is reasonable to generally use the term “venom” for their oral products with the understanding that the traditional biological criteria assigning the term is unknown for a significant number of taxa.

Table 2 Representative components isolated from venoms/oral secretions of non-front-fanged colubroid snakes (NFFC)

NFFC taxa ^a	Isolated/ characterized component(s)	Reference	Comments
Family, Subfamily [1]			
Colubridae, Colubrinae			
Mangrove snake, or ringed cat snake, <i>Boiga dendrophila</i>	Three-finger fold postsynaptic neurotoxin [3FTX] ("denmotoxin")	[34, 61]	Primarily avian-specific postsynaptic neurotoxin; Mr 8.5 kDa that contains five disulfides. Aside from a conserved leader signal sequence, its basic genetic organization (e.g., arrangement of untranslated and translated sequences) differs from that of elapid three-finger toxins. This toxin is unlikely to have clinical importance
Brown tree snake, <i>Boiga irregularis</i>	Unusual three-finger fold postsynaptic neurotoxin ("irditoxin")	[61]	Novel 17.1 kDa disulphide-linked, heterodimeric structure; approximately threefold more active in vitro at the avian neuromuscular junction than in the rat phrenic nerve preparation; selective toxicity for lizards and birds. This toxin is unlikely to have clinical importance
Brown tree snake, <i>Boiga irregularis</i>	"Myotoxic fraction" (containing 2 proteins)	[62]	Fraction contained two proteins, 14.5 kDa and 17 kDa; i.p. injection into mice caused myoglobinuria due to multifocal myofiber degeneration and necrosis. There is currently no evidence supporting medical importance of these proteins
Radiated ratsnake, copperhead ratsnake, <i>Coelognathus radiatus</i>	Three-finger fold postsynaptic neurotoxin ("colubritoxin")	[63]	An 8.5 kDa 3FTX; notable structural homology with elapid 3FTX; produces reversible antagonism in the chick biventer cervicis muscle preparation. There is currently no evidence supporting medical importance of this toxin
Boomslang, <i>Dispholidus typus</i>	"Coagulant principle"	[64, 65]	The ≈ 67 kDa "procoagulant principle" reported by Hiestand and Hiestand [29] is probably the same or a similar molecular species noted by Guillin et al. [28] with powerful prothrombin-activating activity. This toxin very likely plays an important role in the life-threatening clinical envenoming that can follow bites by this species
Boomslang, <i>Dispholidus typus</i>	P-III/P-IV snake venom metalloprotease [SVMP] ("dispholysin A")	[66]	The 65 kDa species cross-reacted with the P-III hemorrhagic SVMP from <i>Bothropoides (Bothrops) jararaca</i> (Oliveira et al. [31]) venom. This toxin very likely plays an important role in the life-threatening clinical envenoming that can follow bites by this species (see the previous entry)
Kirtland's twig, vine or bird snake, <i>Thelotornis kirtlandii</i>	Procoagulant	[68]	The ≈ 85 kDa procoagulant (pI 5.25) was partly characterized from a "venom gland" extract and found to be a direct prothrombin activator. This fraction, as well as other similar procoagulant components in combined action with metalloproteinases, causes the life-threatening clinical effects in patients after being bitten by this species
Sonoran lyre snake, <i>Trimorphodon biscutatus lambda</i> [<i>Trimorphodon lambda</i> DeVitt et al., 2008]	Phospholipase A ₂ [PLA2] ("trimorphin")	[69]	Some conserved structural features of the Group IA PLA2 were present in this 13.99 kDa PLA2 and suggested that there was a close relationship with some hydrophiine elapid PLA2. There is currently no evidence supporting medical importance of this PLA2, but, to date, there are also very few well-documented bites by this species, and none are medically significant

(continued)

Table 2 (continued)

NFFC taxa ^a	Isolated/ characterized component(s)	Reference	Comments
Dipsadidae			
Puerto Rican racer, <i>Borikenophis</i> [<i>Alsophis</i>] <i>portoricensis</i>	P-III metalloproteinase ("alsophinase")	[70]	α -fibrinogenolytic 56 kDa polypeptide with hemorrhagic activity in mice that has 67% primary sequence homology with metalloproteinase from <i>P. olfersii</i> venom; of unknown clinical significance
Mountain keel back, <i>Helicops angulatus</i>	Cysteine-rich secretory protein [CRISP] ("helicopsin")	[71]	The 20 kDa CRISP was toxic to mice. There is currently no evidence supporting medical importance of this toxin, but there are also very few well-documented bites by members of this genus
<i>Philodryas olfersii</i>	Myotoxin	[72]	The 20 kDa (pI 4.8) toxin produced myolysis and extensive widening of the intercellular spaces with partial or total loss of transverse muscle striations in the muscle periphery. See above entry for additional comments regarding possible medical importance of this toxin
Patagonian racer, <i>Philodryas</i> <i>patagoniensis</i>	Hemorrhagic, α - fibrinogenolytic metalloprotease ("patagonifibrase")	[73]	An acidic 53.2 kDa SVMP that can directly cleave fibrinogen. The venom/oral secretion of this species also contains other metalloproteases, CRISPs, 3FTX, and a rich complement of other biologically active proteins. Although several authors relate these and similar toxins of <i>Philodryas</i> spp. to clinical effects in bitten victims, to date, there is no clear evidence of this linkage
Natricidae			
Tiger keel back, or Yamakagashi, <i>Rhabdophis tigrinus</i>	Metalloproteinase ("38 kDa metalloproteinase")	[74]	The authors noted that the regulatory mechanism of this novel proteinase suggested that it was more likely a matrix metalloproteinase, rather than a SVMP. The venom of this species and that of the congener <i>R. subminiatus</i> (red-necked keel back) has several medically important toxins such as prothrombin activators, and these combined with the action of metalloproteinases likely result in the life-threatening hemorrhagic effects observed in patients after being bitten by these species
Homalopsidae			
Dog-faced watersnake, <i>Cerberus</i> <i>rhynchops</i>	"Ryncolins" (unconfirmed/ unknown function)	[20]	Based on their structural homology with mammalian ficolins, OmPraba et al. [21] hypothesized that ryncolins may act as platelet aggregators and/or complement activators
Lamprophiidae, Psammophinae			
Montpellier snake, <i>Malpolon</i> <i>monspessulanus</i>	Hemorrhagic toxin ("Fraction CM-6")	[13]	This 24 kDa component produced pulmonary hemorrhage in mice but did not cause local hemorrhage when administered intradermally. Currently, there is no evidence that this toxin is medically important
African beaked snake, <i>Rhamphiophis</i> <i>oxyrhynchus</i>	Postsynaptic neurotoxin, 3FTX ("rufoxin")	[75]	Novel toxin (molecular mass \approx 10–12 kDa) lacking N-terminus homology with elapid 3FTX; produces reversible antagonism in the chick biventer cervicis muscle preparation. As with most NFFC toxins characterized to date, there is currently no evidence that "rufoxin" has any medical importance, but there are also no well-documented clinically significant bites by this species

^aTable modified after Weinstein et al. [1], and used with permission

Medical Risks Posed by Most NFFC Species Have a Notably Limited Evidence Base

There is much confusion and disseminated incorrect information about the known and possible medical risks posed by some NFFC. This includes premature theorized risk assignment suggested by wholly incomplete or inapplicable information such as chromatographic detection of toxin classes in limited venom samples, inaccurate comparisons between experimental murine lethal potency studies of venoms from FFC and NFFC, and unsupported propagation of anecdotal and second- or thirdhand, as well as blatantly false reports of medically significant, even fatal, bites from various NFFC taxa [1, 27]. This incorrect and often misleading information is increasingly found on the Internet, in popular publications, as well as in some sensationalist television documentaries, and even in the scientific and medical literature.

When considering only the well-documented medical literature (meaning, high-quality

evidence-based clinical reports prepared and reported by medically qualified authors), to date, four species of NFFC have caused human fatalities, while three others have inflicted bites capable of causing serious and potentially life-threatening systemic pathology (Table 3). However, most well-documented bites from NFFC cause only minor medically insignificant, local effects (Fig. 9). Nonetheless, most taxa are of unknown medical significance because there have been no adequately documented cases delineating the clinical symptoms and pathophysiological effects of their bites. Previously, only a limited number of published cases have been subjected to medically qualified review, and these tended to be regionally focused [28, 29]. A recent comprehensive analysis of the available evidence for medical significance of NFFC found a limited database with few well-documented cases containing detail sufficient for assignment of risk to a relatively small number of NFFC [1, 3]. Thus, medically reliable risk assessments and envenoming management recommendations can only be provided for a relative handful of NFFC species. Many published

Table 3 The medical significance of some representative non-front-fanged colubroid snakes (NFFC)^{a,b}

NFFC taxa (family, subfamily)	Hazard index ^c	Basic medical management strategy ^d	Evidence level ^e
Boomslang, <i>Dispholidus typus</i> (Colubridae, Colubrinae) Cape twig or vine snake, <i>Thelotornis capensis</i> (Colubridae, Colubrinae) Kirtland's twig or vine snake, <i>T. kirtlandii</i> (Colubridae, Colubrinae) Tiger keel back or Yamakagashi, <i>Rhabdophis tigrinus</i> (Natricidae) Red-necked keel back, <i>R. subminiatus</i> (Natricidae) Sri Lankan keelback, "blossom" or "flower krait," or "flower blossom" snake (<i>Balanophis ceylonensis</i> , Natricidae)	1	<i>Effective antivenoms are available for D. typus and R. tigrinus. Antivenom raised against R. tigrinus venom should be used to treat serious envenoming by R. subminiatus as it probably provides paraspecific protection. Due to a robustly close taxonomic relationship, it would be reasonable to use R. tigrinus antivenom for a potentially life-threatening envenoming by B. ceylonensis, while remaining cognizant that there is no evidence base to specifically support its efficacy There is no antivenom for envenoming by Thelotornis spp. and there are no antivenoms that provide paraspecific protection (including those mentioned above). Treatment consists of replacement therapy^f only. Replacement therapy may also be needed for the aforementioned species in addition to antivenom on a case-by-case basis. Significant bites from any of these species must be considered life threatening The use of heparin, antifibrinolytics, vitamin K, corticosteroids, etc. is positively contraindicated due to an unfavorable risk vs. benefit profile</i>	Level III Antivenom for <i>D. typus</i> and <i>R. tigrinus</i> envenoming IE <i>R. tigrinus</i> antivenom for <i>R. subminiatus</i> or <i>B. ceylonensis</i> envenoming IE Replacement therapy for treatment of <i>Thelotornis</i> spp.

NFFC taxa (family, subfamily)	Hazard index ^c	Basic medical management strategy ^d	Evidence level ^e
Monpellier snake, <i>Malpolon monspessulanus</i> (Lamprophiidae, Psammophinae) Brown tree snake, <i>Boiga irregularis</i> ^g (Colubridae, Colubrinae) Lichenstein's racer, <i>Philodryas olfersii</i> (Dipsadidae)	2–3	Closely monitor neurological signs in those bitten (especially pediatric patients) by <i>M. monspessulanus</i> and <i>B. irregularis</i> and coagulation panels in those bitten by <i>Philodryas</i> spp. Consider the use of neostigmine if paralytic features (e.g., ptosis, dysphagia) develop. <i>Do NOT give antivenom of any kind</i> . Carefully scrutinize the wound and provide early wound treatment if clinically indicated	IE
False water cobra, <i>Hydrodynastes gigas</i> (Dipsadidae) Western hognose snake, <i>Heterodon nasicus</i> (Dipsadidae) Mangrove snake, <i>Boiga dendrophila</i> (Colubridae, Colubrinae)	3	Any patient presenting with a clinically significant bite should be observed in a well-equipped facility. <i>Do NOT give antivenom of any kind</i> . Carefully scrutinize the wound and provide early wound treatment if clinically indicated. There is no current convincing evidence of systemic effects occurring after the bites of any of these taxa, but patients should be carefully assessed and bites from large specimens may produce moderate local “envenoming”	Level III
Garter and ribbon snakes, <i>Thamnophis</i> spp. (Natricidae) and many other taxa of diverse taxonomic affinities	4	Minor local wound care only	Level III

IE insufficient information to provide an evidence ranking

^aThis list contains only some representative species, and risk assignment can only be accomplished for relatively few NFFC. This is due to the absence of acceptably documented clinical information, species identification, and/or other criteria that would constitute a basis for accurate assessment and Hazard Index assignment, as suggested by Weinstein et al. [3]. The presence in ophidian oral secretions/venoms of toxins and/or their transcripts are insufficient criteria for assessment of possible medical significance of a given species as these may be prey-specific and/or may have no medical relevance due to multifactorial influences relevant to both the snake and human victim. There are very likely a number of other NFFC that may have medical significance under some multifactorial circumstances

^bTable after that in Weinstein et al. [1]

^cHazard index is defined as: Level 1 – Serious and potentially fatal envenoming is possible; Level 2 – Systemic envenoming is possible, but uncommon; Level 3 – Usually mild-moderate local effects and usually associated with a protracted bite; Level 4 – Most commonly medically insignificant; larger specimens may inflict minor local effects [3]

^dThis only lists the essential basic management approach; specific cases may require additional interventions. See Weinstein et al. [3] for a detailed discussion of diagnosis, laboratory investigations, and management of medically significant NFFC bites

^eLevels of evidence are defined as follows: I. Evidence obtained from at least one properly randomized controlled trial; II-1. Evidence obtained from well-designed controlled trials without randomization; II-2. Evidence obtained from well-designed cohort or case-control analytic studies, preferably from more than one center or research group; II-3. Evidence obtained from multiple time series with or without the intervention. Dramatic results in uncontrolled could also be regarded as this type of evidence; III. Opinions of respected authorities based on clinical experience, descriptive studies and case reports, or reports of expert committees. IE – there is insufficient quality information to provide an evidence ranking. All of the included current information determining evidence levels for diagnosis and management of NFFC envenoming is derived from case reports, low-powered, small series, respected opinion, and personal experience

^fReplacement therapy consists of provision of packed erythrocytes, platelets, cryoprecipitate or fresh frozen plasma, etc. The use of these in coagulopathic envenoming carries risk and remains controversial. Therefore, this should be considered per clinical need (e.g., bleeding risk) on a case-by-case basis

^gThis hazard assignment applies only to the nonnative *B. irregularis* populations that were introduced on Guam and several other Micronesian islands during World War II. These snakes generally reach larger size than that of most *B. irregularis* found in their natural range (coastal New South Wales, Queensland and Northern Territory, Australia; New Guinea, Sulawesi, Togian Islands, Indonesia)

Fig. 9 A typical example of a medically insignificant bite from a NFFC. The effects are limited to minor puncture wounds, slight erythema, and minor bleeding. Some bites also cause mild, transient edema localized to the wound site. The pictured bite was caused by a Kenyan specimen of the speckled sand racer, *Psammophis punctulatus* (Lamprophiidae, Psammophiinae) (Photo copyright to David A. Warrell)

cases of bites by NFFC contain low-quality evidence, and the poor documentation complicates the assessment of evidence-based risk of many species.

This chapter will provide a brief overview of medically important information about those selected NFFC for which there is some reasonable quality evidence.

Clinical Presentation and Evidence-Based Assessment of Medical Risks of NFFC

The medical significance of the majority of NFFC taxa is unknown, and a recent comprehensive analysis of this question emphasized the paucity of well-documented medically significant bites, or “envenoming,” inflicted by NFFC in the literature [3]. Aside from several NFFC that have been carefully observed to inflict serious, life-threatening, and/or fatal envenomings (e.g., *R. tigrinus* [Fig. 5], *R. subminiatus* [Fig. 6], *D. typus* [Fig. 3], *Thelotornis* spp. [Fig. 4], *Balanophis ceylonensis* [Fig. 10]), bite cases ascribed to NFFC predominantly are poorly documented, rely on anecdotal

Fig. 10 The rare Sri Lankan flower blossom krait, *Balanophis ceylonensis* (Natricidae), a Hazard Index 1 species that is closely allied with *Rhabdophis* spp. A recent index case documented the potentially life-threatening coagulopathic effects that may occur from an envenoming by this species. Although there is no clinical evidence that

antivenom against *R. tigrinus* has efficacy in treating envenoming by this snake, any life-threatening envenoming by this taxon should be treated with this antivenom because the benefit to risk ratio is likely favorable, and it could have good therapeutic efficacy (Photo copyright to Daniel E. Keyler)

Fig. 11 The false water cobra, *Hydrodynastes gigas* (Dipsadidae), is a large, heavy bodied species that is popular in private collections particularly in the USA and Europe. These snakes can inflict a painful bite, which can include some locally progressive edema. A published report that described much delayed more serious effects has been critically analyzed, and it was concluded that the

victim experienced somatosensory amplification and/or panic disorder. However, even small specimens such as the juvenile pictured here can inflict painful, edematous bites and should not be taken lightly. Management is restricted to supportive care and meticulous wound management (Photo copyright to David P. Richards)

information, and/or are authored/analyzed by nonmedically qualified contributors, often by the victim himself/herself with highly subjective impressions. Partly as a result of unsupported speculation, a number of taxa have acquired an unwarranted reputation for inflicting potentially fatal bites or have been prematurely viewed as hazardous [1, 3, 27]. Conversely, other NFFC may be prematurely dismissed as “harmless,” when in fact their medical significance is unknown [3, 27]. Many NFFC are popular in private collections, and speculation (especially on the Internet) about their possible ability to inflict medically significant bites is often replete with incorrect information and assumption. Mouse lethal potency studies of venom/oral secretions of NFFC have been used as a basis for such predictions (e.g., that of the false water cobra, *Hydrodynastes gigas*, Dipsadidae; 2.0 [i.p.]–9.4 [s.c.] mg/kg [30]; see Figs. 11 and 12) by comparison with medically important front-fanged species such as the timber rattlesnake (*Crotalus horridus*, Viperidae, Crotalinae) (2.63–3.31 [i.p.]–9.15 [s.c.] mg/kg [31–33]) [1, 18]. There are also other inappropriate and misleading pharmacological comparisons such as neurotoxic potency based on in vitro nerve twitch electrophysiological

Fig. 12 Another member of the genus *Hydrodynastes* is *H. bicinctus* (Herrmann's water snake); this species is infrequently illustrated and, although sought by collectors, is uncommon in private collections. Medical professionals treating bites from privately maintained NFFC must remain cognizant of the occasional acquisition by collectors of species that are often infrequently displayed in zoological parks (Photo copyright to Pedro H. Bernardo)

preparations testing powerful elapid venoms (e.g., that of the common death adder, *Acanthophis antarcticus*, Elapidae) directly compared with those of some NFFC. This is misleading as it simply relates the magnitude of antagonism observed from in vitro nerve-muscle preparation

assays to potential lethal potency in vivo. Such observations can reflect the medical importance of highly potent venoms that contain a high proportion of medically important toxins in a potentially large volume of venom delivered under high pressure with canaliculated fangs, but it is misleading to compare these with NFFC toxins [3, 18]. Aside from the differences in delivery systems and glandular storage/secretion characteristics, another contributing factor to such an inappropriate comparison is the receptor specificity of some colubroid toxins (e.g., greater affinity for avian- or lizard-specific cellular targets as mentioned previously). Most NFFC venoms/oral secretions that have been assayed to date exhibit modal or low lethal potencies in the murine model (see Weinstein and Kardong [10] and Weinstein et al. [3] for comparison of lethal potencies). However, whenever possible, laboratory investigation of NFFC venom lethal potency or other biological activities should consider prey preferences of the species of interest, as some do have high toxicity and potency in some avian and lizard models [34–36], a concern that is also often unaddressed in some studies of FFC venoms.

Verified identification of snake taxa responsible for a given medically significant snakebite is often challenging, but, with bites inflicted by NFFC, this can be a major issue, as it can confuse the assignment of medical risk to the correct species. Aside from the common problem of correct identification even to genus, a significant number of NFFC species may appear similar to FFC, especially to an untrained eye, and some appear as “mimics” of medically significant FFC. This important issue has been discussed and illustrated elsewhere (e.g., Campbell and Lamar [37], Weinstein et al. [1, 3, 27]; see Figs. 13 and 14).

The explosion of popularity of reptiles (especially snakes) and amphibians in the pet industry and among amateur enthusiasts increases the importance of these considerations [1]. It is important that medical professionals are better informed about the potential clinical importance of NFFC termed “mildly venomous” or of those with unknown toxicity [1, 3, 18]. The medically relevant toxicity of oral secretions/venoms in the vast majority of NFFC remains unknown, but

Fig. 13 The false coral snake (*Erythrolamprus aesculapii*, Dipsadidae), an example of a NFFC, “mimic” of a medically important *Micrurus* spp. (Elapidae). Compare with the next figure. False coral snakes occasionally are handled carelessly (especially because they can be easily confused with *Micrurus* spp.), and a few reports describe mild local effects after bites by several species. It should be noted that the oft repeated aphorism, “red to black venom lack, red to yellow, kill a fellow,” and its variants only is *somewhat* applicable in the continental USA, and occasional *Micrurus* spp. specimens in the USA may have wholly different color phases (e.g. melanistic, aberrant patterns). Latin American *Micrurus* spp. do not exhibit any such defined pattern association with the “venomous state” (Photo copyright to Fabio Bucarechi)

there are likely taxa of several subfamilies that secrete venoms of clinical importance. Some large adult NFFC with modal or low lethal potency may also pose a risk to pediatric or geriatric patients and to those with chronic illness and/or multiple comorbidities [1, 3, 18]. Therefore, a medically qualified, patient-centered, evidence-based approach is crucial when conducting a medical risk assessment of NFFC based on published information, as well as personal clinical experience [3].

An Overview of Medically Important NFFC and Management of Their Bites

A patient-centered critical analysis of bites inflicted by NFFC found that only a small number of species (around 120 taxa) have been documented with clinical content acceptable for qualified medical assessment (Table 3) [1, 3]. Most cases were of insignificant or mild local effects (e.g., puncture wounds, abrasions, lacerations, limited bleeding, and mild edema; see Fig. 9). Only

Fig. 14 A Brazilian specimen of the southern coral snake, *Micrurus frontalis* (Elapidae), a medically important FFC that is responsible for a significant number of postsynaptic neurotoxic envenoming particularly in Brazil. These snakes can be (and have been) mistaken for several species of medically unimportant NFFC, which possess very similar pattern colors, and are thus “mimics” (see Fig. 13). Conversely, the NFFC mimics can be likewise mistaken

for several *Micrurus* spp. Accurate identification of a snake deemed responsible for a presenting patient’s bite is essential because the absence of correct identification can prevent the delay of life-saving intervention or, in contrast, may cause the administration of unnecessary treatments thereby exposing the patient to avoidable risk (Photo copyright to Fabio Bucarechi)

approximately 24 species-inflicted bites produced medically significant effects, and bites from an additional 31 taxa have produced nonprogressive mild local pathology insufficient to be tabulated as “medically significant,” but were ranked because of the near significance of their respective presentations. A small number of reports described bites producing moderate local effects that occasionally resulted in persistent symptoms.

The available information about the evidence-based medical risks posed by NFFC taxa are most conveniently considered by grouping those with a reliable database into broad categories defined by their degree of medical risk (Table 3). Thus, these groups are defined as “Hazard Index” 1–4.

Hazard Index 1

The life-threatening risks of venomous colubrine genera such as *Dispholidus typus* and *Thelotornis* spp. (African bird, twig, tree, or vine snakes) and

that of natricids such as two taxa of Asian keelbacks or flower snakes, *Rhabdophis* (*R. tigrinus*, tiger keelback or Yamakagashi, and *R. subminiatus*, red-necked keelback; see Figs. 3, 4, 5, and 6), are well established by unequivocal clinical evidence (Table 3). Bites from these species cause consumptive coagulopathy/disseminated intravascular coagulopathy (DIC) and hemorrhagic diathesis, complicated in some cases by acute kidney injury (most likely from prerenal effects, although direct nephrotoxicity is possible), and are thus designated “Hazard Index or Level 1” (Table 3) [1, 3].

Recently, a single report [38] carefully detailed a patient envenomed by the uncommon and poorly known monotypic natricid, *Balanophis ceylonensis* (Sri Lankan “flower” or “blossom krait”; see Fig. 10). The patient developed a serious consumptive coagulopathy with active bleeding [38], which is similar to that caused by envenoming by *Rhabdophis tigrinus* or *R. subminiatus*, close taxonomic relatives of this little-known taxon.

Fig. 15 The genus *Rhabdophis* (Natricidae) contains approximately 21 species, and two of these, *R. subminiatus* and *R. tigrinus*, are medically significant with the latter responsible for human fatalities. However, the medical relevance of the remaining members of the genus currently is unknown. Pictured is *R. conspicillata* (red-bellied keelback; Photo copyright to Indraneil Das)

Fig. 16 Another little-known *Rhabdophis* spp., *R. murudensis* (Gunung murud keelback). The medical significance of this taxon remains unknown (Photo copyright to Indraneil Das)

The common name used for *B. ceylonensis*, “flower krait,” should not lead to confusion of this NFFC of the family Natricidae with the elapids, *Bungarus* spp. (kraits). Shared or similar common names are often used for vastly different snakes, and identification of any snake involved in snakebite accident must be determined, whenever possible, by an individual qualified to identify the specimen when available or from a reasonable quality photo. In some cases when there are no available data about the snake, a combination of clinical manifestations and the most likely snake species found in the region of the incident may provide some guidance for presumptively assigning the taxon responsible for the bite.

It should also be noted that there are some 21 taxa of *Rhabdophis* (see Figs. 15 and 16 for

additional examples of *Rhabdophis* spp.) and another closely allied monotype, *Pararhabdophis chapaensis* (Vietnam water snake). Any possible medical significance of these species currently remains uncharacterized and unknown, but all of these snakes must be considered potentially medically important (e.g., capable of inflicting a life-threatening envenoming) until proven otherwise.

Toxins of Hazard Index 1 NFFC and the Pathophysiology of Envenoming

As noted, the clinical effects that result from a significant envenoming by snakes in this group consist of consumptive coagulopathy, generation of thrombi, active bleeding, visceral hemorrhage, thrombocytopenia, intravascular hemolysis,

elevated liver enzymes, notable ecchymoses (particularly severe in dependent anatomical sites; see Fig. 18), and, in some cases, acute renal injury (Table 3, Fig. 17). Although kidney injury most commonly complicates the severely envenomed patient, it may occur in patients who have what appears clinically to be a moderate envenoming and may be related to premorbid occult renal disease and/or individual venom variability or other factors. To date, catastrophic hemorrhage and bleeding has been reported in serious envenoming from *Dispholidus*, *Thelotornis*, and *Rhabdophis tigrinus*, while *R. subminiatus* and the single-documented serious envenoming by *Balanophis* have produced what most

parsimoniously appear to be self-limited consumptive coagulopathy with less severe bleeding [1, 3, 38]. However, the latter two taxa certainly must be considered as potentially lethal species, and there is the possibility that replacement therapy may have lessened the severity of the venom disease, although there is currently no firm evidence to support this.

To date, the toxinology of these medically important species has only been marginally explored. Snake venom metalloproteases (SVMP) and prothrombin activators have been characterized from the venoms of *Dispholidus*, *Thelotornis*, and the two taxa of *Rhabdophis* (Table 2, Fig. 17). It is important to note that

Fig. 17 Simplified outline of the coagulation cascade. Studied venoms and/or toxins of the natricids, *R. tigrinus* and *R. subminiatus*, and the dispholidine colubrids, *D. typus* and *T. kirtlandii*, act as prothrombin activators that function in concert with rhexic hemorrhagins (snake venom metalloproteases, SVMPs, see Table 2). This combined action causes a consumptive coagulopathy and proteolytic disruption of the microvasculature endothelial

basement membrane resulting in leakage from the vascular bed, active, clinically significant bleeding and hemorrhage. Patients seriously envenomed by these Hazard Index 1 species often exhibit extensive ecchymoses especially in recumbent or dependent anatomical sites, bleeding, AKI, thrombocytopenia, and intravascular hemolysis (Figure copyright to Julian White)

Fig. 18 A historical example of extensive dependent ecchymoses in a patient with a life-threatening envenoming by *D. typus* (From EU Schmid Geneeskunde 1962;4)

without the SVMP, the procoagulant, fibrinogen-consuming actions of the venom prothrombin activators would not likely induce the hemorrhagic diathesis commonly featured in serious envenoming by these species, as the SVMP probably cause rhexic disruption of the endovascular matrix, thus allowing uncontrolled vascular leakage per defibrinated blood. It is also likely that other yet uncharacterized venom components play a role in the complex pathophysiological effects of these venoms [3]. Although the toxinology of *B. ceylonensis* venom has not yet been reported, it is likely that it also contains some components similar to those of the medically important and allied *Rhabdophis* spp. This close taxonomic relationship had previously prompted caution about the potential medical significance of *B. ceylonensis* [3].

Important Features of Management of Medically Significant Hazard Index 1 Envenoming*

The essentials of evaluating a patient envenomed by any of these snakes share common features to that of any bite by a venomous snake and are summarized ahead in section “[Medical Risks Posed by Most NFFC Species Have a Notably Limited Evidence Base](#)” (Table 3). *It must be noted that all recommendations included here for management of Hazard Index 1–4 NFFC bites are based on Evidence Level 3.* [*Evidence

Level 3 (see Table 3) is assigned as the evidence for diagnosis and management of NFFC envenoming and is wholly based on case reports; low-powered, small series; respected opinion; and personal experience].

- In the event of a serious envenoming by either *Dispholidus*, *R. tigrinus* or *R. subminiatus*, or *B. ceylonensis*, a prime and early consideration is the need to locate at least 1–2 ampoules of monovalent antivenom (AV) for either *D. typus* (*D. typus* monovalent, South African Vaccine Producers [SAVP, 1 Modderfontein Road, Sandringham, Johannesburg, South Africa, Telephone +27 11 882 9940, Fax +27 11 882 0812, E-mail: savpunit@global.co.za/savpqual@global.co.za], formerly South African Institute for Medical Research [SAIMR]) or *R. tigrinus* (*R. tigrinus* antivenom, Japan Snake Institute, Yabuzuka-honmachi, Nittagun, Gunma Prefecture 379–2301, Japan, Telephone +81 277 78 5193, Fax +81 277 78 5520, e-mail snake-a@sunfield.or.jp). Presently, these are the only commercially prepared and effective AV for any NFFC envenoming and are notoriously difficult to rapidly procure from the manufacturer, although some American and European commercial venom suppliers occasionally have a small on-hand supply.

These AV must only be used for the following species (also see Table 3):

SAVP monovalent anti-*D. typus* AV (Equine, F(ab)₂, liquid preparation, 10 mL, “pepsin refined,” contains 0.35% cresol) – *may only be used to treat envenoming by D. typus. It is ineffective against all other species tested to date including Thelotornis spp.* There have been multiple well-documented fatalities from *D. typus* envenoming that have been recorded since the early twentieth century, and any patient with coagulopathy and active bleeding should receive this AV whenever possible and as promptly as is feasible, a major reason to immediately seek a supply when presented with a patient envenomed by this taxon. This AV has been effective up to 5 days post envenoming.

Japan Snake Institute anti-*R. tigrinus* AV (Caprine or lepid, F(ab)₂, lyophilized, constitute to 10 mL, pepsin digested/salt precipitated) – may be used to treat envenoming by *R. tigrinus*, *R. subminiatus*, and *B. ceylonensis*. This AV has effectively reversed envenoming by the homologous species, while all envenoming by *R. subminiatus* have been successfully managed by replacement therapy or without specific intervention. There is strong likelihood that this AV affords some paraspecific protection against *R. subminiatus* venom. Likewise, because of the close taxonomic alliance among *Rhabdophis* and *Balanophis* (which previously was placed in the genus *Rhabdophis* until it was reassigned as a monotype), there is a reasonable likelihood that *R. tigrinus* AV might have paraspecificity for *B. ceylonensis* venom. Therefore, in the event of a life-threatening envenoming by *B. ceylonensis*, provision of this AV should be considered and provided if it can be procured with the understanding that there is no evidence for or against its use for envenoming by either *R. subminiatus* or *B. ceylonensis*. Patients or their legal family proxy must be fully informed of the essential facts, as well as potential risks and benefits posed by the use of these AV.

- Complete patient medical and social history must include any recent dental work (including dental hygienic procedures such as uncomplicated scaling), recent hospitalization, and/or recent outpatient venipuncture or other procedures; tattoos, piercings, and complete medication (especially anticoagulants, nonsteroidal anti-inflammatories {NSAIDs}); and recreational drug/alcohol use.
- It is important to determine whether the patient maintains a captive reptile collection (this obviously includes lizards), works with snake venoms, or has in the past. Likewise, any previous medically significant snakebites and any previous treatment with AV are essential information. Some of this information (especially the history of involvement in captive reptile husbandry) is occasionally neglected or omitted. Previous exposure to squamate reptile oral secretions (not solely venoms), shed skins, body fluids, and defecate (including solid urates) may predispose to variable sensitization to ophidian antigens, some of which are shared between venoms and body fluids and even occur in excreta (especially in FFC who shed fangs and swallow them, thus later appearing in their excreta). This is not only a laboratory phenomenon, as there is a gathering body of information derived from clinical reports that suggest a role of ophidian antigen atopy in the severity/clinical manifestations of envenoming or even in the degree of individual reactivity to otherwise clinically unimportant NFFC bites [3, 26]. In a small series of eight patients envenomed by either the FFC, *Vipera berus*, or *V. aspis* (respectively, the European viper and the European asp, Viperidae, Viperinae), the development of systemic envenoming was correlated in seven with a sensitized state supported by elevated IgE levels and venom skin testing [39]. The clinical manifestations of a local envenoming by a Hazard Index 3 NFFC, *Heterodon nasicus* (Western hognose snake, Dipsadidae, Fig. 19; also see Fig. 20), included some effects strongly suggestive of localized type 1 hypersensitivity (Figs. 21 and 22) [26]. Cutaneous type 1 hypersensitivity can cause local effects

Fig. 19 The Western hognose snake, *Heterodon nasicus* (Dipsadidae), is a popular species among private collectors in the USA and Europe. This benign species puts on an impressive display of huffing, mock striking and, if all else fails, shamming death. Bites are rare, and almost always result from exposure of the handling person to food items or occur while offering food to the snake. There are only a handful of well-documented bites and most consist of mild local edema and transient pain/bleeding. A few cases have included progressive edema, significant pain, and blistering that resembles mild-moderate local envenoming from a

crotaline viperid (see Figs. 21 and 22). Some of the effects closely resemble localized, cutaneous Type I hypersensitivity, and it is likely that some private collectors become to some extent sensitized to products of captive husbandry (venoms and other oral products, snake defecate, body fluids incorporated on shed skins, etc.), as many contain shared antigens. There is no reason for any considered legal regulation of these or other NFFC that very rarely inflict medically significant bites (Photo copyright to Barney Oldfield)

Fig. 20 The Eastern hognose snake, *Heterodon platirhinos* (Dipsadidae), another of the four species in the genus, is also popular in captive collections but is less frequently maintained because of its more commonly restricted diet (anuran amphibians, particularly toads [e.g., *Anaxyrus* spp.], while *H. nasicus* readily accepts rodents). There are only a couple of well-documented accidental “bites” from this species, which occurred from penetration of an enlarged posterior maxillary tooth (which are nongrooved) into a digit or hand (Photo copyright to Pedro H. Bernardo)

that may resemble the local effects of some snakebites (e.g., erythema with some progression, edema, blistering). This factor that contributes to the clinical manifestations of some snakebites has unfortunately received little qualified attention and/or has been incorrectly dismissed in the literature or on the Internet by medically unqualified opinion. Thus, the related possible previous exposure to squamate reptiles and their antigens is an important part of the collected history.

- Patients with any significant cardiovascular comorbidities (including poorly managed hypertension) should, whenever possible, have cardiac telemetry and regular examination. Patients with preexisting renal disease should have careful, serial renal output and urine protein and creatinine measured. Even simple serial dipstick measurement can detect early, increasing proteinuria.
- Any patients with relevant history, as noted above, should have careful serial examination

Fig. 21 Effects of local envenoming 72 hours after a protracted bite by a Western hognose snake, *H. nasicus*. The patient was bitten while offering food to the snake, and the pictured effects progressively developed over several hours postbite. Note the extensive erythema, edema, and blistering, which could be misinterpreted as resulting from a mild-moderate crotaline viperid envenoming. Some of the effects likely were a result of cutaneous Type I hypersensitivity (also see Fig. 22; Photo copyright to Daniel E. Keyler)

Fig. 22 Effects of local envenoming five days after a protracted bite by a Western hognose snake, *H. nasicus*. Note the focal blistering distant from the bite site (also see Fig. 21). The patient's recovery was not complete for several months (Photo copyright to Daniel E. Keyler)

of the involved anatomical site (careful serial examination of the gingival sulci, recent procedure sites, recent tattoos, etc.) for bleeding. Avoid extended recumbence on a given anatomical region because this may result in extensive ecchymoses; shift the patient periodically and support with wedge pillows as needed.

- Hazard Index 1 NFFC-envenomed patients require serial laboratory testing including activated partial thromboplastin time (aPTT), international normalized ratio (INR), fibrinogen, complete blood count including platelets, and creatinine and urine protein (as noted above). Initial laboratory tests should also include liver function tests, electrolytes,

blood urea nitrogen, creatinine, and creatinine phosphokinase. Cardiac enzymes (e.g., troponin I) should be included for any envenomed patient with a significant cardiovascular history or any with signs/symptoms suggestive of cardiac involvement. Measured 24 h urine creatinine/albumin should be carefully monitored in any patient with previous (e.g., diabetic nephropathy) or evolving evidence of renal insult.

- A substantial subgroup of patients with life-threatening Hazard Index 1 envenoming may exhibit severe thrombocytopenia, intravascular hemolysis, and/or DIC with active bleeding and/or massive hemorrhage. Some of these patients may require replacement therapy, depending on the specific clinical circumstances (risk of cerebral hemorrhage, massive

ongoing bleeding, etc.) and the likely risk vs. benefit of replacement. There are insufficient clinical data supporting the provision of replacement therapy to patients with sustained consumptive coagulopathy caused by life-threatening envenoming from Hazard Index 1 dispholidines (*Dispholidus* and *Thelotornis*) or natricids (*R. tigrinus*, *R. subminiatus*, nor also in the rare event of a serious envenoming by *B. ceylonensis*) [1, 3]. However, considering the probable prolonged action/persistence of some of the venom prothrombin activators and rhexic hemorrhagins, this may present a therapeutic conflict between the need to treat severe thrombocytopenia/bleeding with replacement therapy in order to lessen the risk of a catastrophic hemorrhage and/or life-threatening anemia and to add additional substrate for toxin action (“throwing fuel on the fire”). Therefore, it is advisable to cross and match and have at the ready several units of packed erythrocytes (PRBC), platelets, cryoprecipitate, and/or fresh frozen plasma (FFP), but the need for provision of these should be carefully evaluated on an individual patient basis (see Table 3).

- Seriously envenomed patients with premorbid history of cardiovascular or renal disease should have early cardiology and/or nephrology consults. Patients who might require emergent dialysis or percutaneous coronary artery intervention present special concerns because of the obvious issue of the need for placement of the catheter in the probable setting of consumptive coagulopathy and the concomitant risk of uncontrollable bleeding (see Figs. 23 and 24). When absolutely necessary, vessels that may facilitate control of bleeding (e.g., sufficient surface for application of significant compression) should be chosen for dialysis access, e.g., a peripherally inserted central catheter placed in the superior vena cava or, in some cases, a femoral line.
- It is important to note that there are several *Rhabdophis* spp. that are also poisonous, as they synthesize secretions from nuchal-dorsal glands that contain steroid toxins (bufodienolides) derived from their anuran

Fig. 23 Brisk bleeding from an angiocatheter site on the extremity of a patient with a life-threatening defibrinating coagulopathic envenoming from an Eastern brown snake, *Pseudonaja textilis* (Elapidae), the most medically important FFC in Australia. Medical professionals managing patients envenomed by Hazard Index 1 NFFC or FFC that cause coagulopathic envenoming must very cautiously perform venipuncture and catheter placement and be prepared to aggressively staunch potentially uncontrollable bleeding. Only clinically essential procedures should be performed in these patients and always at sites that allow some direct pressure, as needed to help control bleeding (also see Fig. 24; Photo copyright to Judy Ou)

prey (toads). A handful of cases of toxin ophthalmia have been reported after ocular contamination with their nuchal gland secretions [40]. There are also other NFFC with unknown medical significance (e.g., *Macropisthodon* spp., also Asian natricids that are commonly called “keelbacks”), which possess nuchal glands with so far uncharacterized products. Management of ophthalmia from exposure to these nuchal gland secretions should consist of aggressive decontamination with large volumes of sterile saline, water, or, ideally, ophthalmic buffered eyewash and additional treatments with cycloplegics, antibiotics, and possibly steroids, as clinically indicated (see Chu et al. [41]). Continuous ophthalmic irrigation can be facilitated with employment of an intravenous saline bag or a Morgan lens.

Fig. 24 Expanding hematoma at the site of a venous catheter placed in a patient with life-threatening coagulopathic envenoming from a coastal taipan, *Oxyuranus scutellatus* (Elapidae). If placement of any catheter, especially a central line, is deemed absolutely necessary in a patient envenomed by any Hazard Index I NFFC or FFC capable of inflicting a coagulopathic envenoming, a site must be selected (e.g., a peripherally inserted central catheter [PICC] placed in the superior vena cava or, in some cases, a femoral line) that might facilitate control of active bleeding. Although associated with a lower infection rate than that of PICC/femoral lines, the subclavian or internal jugular routes should be avoided, as these do not allow effective control of the brisk bleeding that is likely to occur under the circumstances of defibrinating coagulopathic envenoming (Photo copyright to Julian White)

Hazard Index 2–3 NFFC: Features of Well-Documented Bites

There are few well-documented data about bites by several NFFC species that have been suspected of inflicting significant local envenoming that in uncommon cases have included systemic effects. However, one of these, the brown tree snake, *Boiga irregularis* (Fig. 25), has been involved in a larger series of extensively documented medically significant bites. This is a consequence of the larger-sized individuals that comprise populations of *B. irregularis*, which were accidentally introduced to Guam and several other Micronesian islands during the Second World War (see Table 3). These snakes constitute a significant medical risk to neonates and infants (especially on Guam) and may rarely inflict bites that cause systemic effects including respiratory

Fig. 25 The brown tree snake, *Boiga irregularis* (Colubridae, Colubrinae). Accidentally introduced to Guam and other Micronesian islands during the Second World War, this invasive species has been subject of largely ineffective control measure by several Acts of Congress. It poses distinct problems wherever it occurs because large individuals attempt predation on infants, and >400 bitten victims have been presented to hospitals on Guam including several infants with systemic effects either from venom and/or constriction by these snakes (Photo copyright to Gordon Rodda)

insufficiency or failure that may be a result of venom or asphyxiation by constriction (*B. irregularis* are powerful constrictors) or a combination of both. Of some 400+ well-documented cases, there are currently known approximately five pediatric patients who exhibited systemic effects after a *B. irregularis* bite [3]. Neurotoxicity in humans is unlikely given that the known neurotoxins of this species are highly specific for lizards and birds, the natural prey of these snakes (see Tables 2 and 3). To date, the etiology of the clinical syndrome involving *B. irregularis* bites inflicted on a small subset of neonates or infants remains incompletely characterized. However, as these snakes can, on very rare occasion, inflict systemic effects in pediatric victims, they must be classed as Hazard Index 2–3.

The two remaining taxa included in this index also have inflicted bites that may cause well-documented, but rare systemic effects. Medically significant bites by the South American green racer, *Philodryas olfersii* (Dipsadidae, Fig. 8), most commonly cause mild to moderate local effects (progressive edema, erythema,

Fig. 26 An example of local effects that commonly occur after a protracted bite from Lichenstein's racer, *Philodryas olfersii* (Dipsadidae). This patient presented with a clear bite site and developed mild local erythema and slight edema (Photo copyright to Fabio Bucaretti)

ecchymoses, and uncommon blistering, Figs. 26 and 27), but at least two well-documented cases showed that widespread ecchymoses distant from the bite site could occur (e.g., Figs. 27 and 28), thus providing evidence of systemic envenoming. However, although there have been anecdotal reports of "coagulopathy" purportedly resulting after medically significant *P. olfersii* bites, so far there has been no documented evidence of coagulopathy in qualified, documented clinical reports [1, 3]. There are approximately 22 species of *Philodryas*, and there is well-documented information regarding the medical effects of bites for only four species with medically significant envenoming reported for only *P. olfersii* and *P. patagoniensis* (Fig. 29) [3]. As previously noted in regard to the unknown medical risks of other species of *Rhabdophis*, the remaining *Philodryas* spp. (e.g., see Figs. 30, 31, and 32) should be viewed cautiously until there is well-documented information about their potential to inflict medically significant envenoming.

Fig. 27 Marked ecchymoses after *Philodryas olfersii* envenoming. The patient was bitten on the right hand and developed extensive, widespread ecchymoses distant from the wound. There was no reported coagulopathy (also see Fig. 28; Photo copyright to Fabio Bucaretti)

Fig. 28 Evidence of systemic envenoming by *Philodryas olfersii*, view of the right axilla of the patient shown in Fig. 27. The patient was bitten on the right hand and developed extensive, widespread ecchymoses distant from the wound. There was no reported coagulopathy (Photo copyright to Fabio Bucaretti)

There is also a single well-documented case [42] of transient cranial nerve (CN) palsies (probably CN III, IV, and VI) that was caused by an envenoming from *M. monspessulanus* (Montpellier snake, Lamprophiidae, Psammophiinae, Fig. 33) in France and established the potential danger associated with bites from this species (also Hazard Index 2–3, Table 3). To date, this is the only NFFC species that has inflicted a

Fig. 29 The Patagonian racer, *Philodryas patagoniensis* (Dipsadidae), another *Philodryas* spp. with some limited medical importance. To date, unlike its congener, *P. olfersii*, there are no well-documented cases of systemic effects after bites by this taxon (Photo copyright to Fabio Bucaretschi)

Fig. 30 Baron's racer, *Philodryas baroni* (Dipsadidae), a *Philodryas* spp. popular in private collections, particularly because of the attractive color variants (e.g., green, blue, etc.). There are only a few documented bites by this species, and so far these have only included mild local effects (Photo copyright to Pedro H. Bernardo)

clinically convincing, thoroughly documented neurotoxic envenoming [1, 3].

Provision of neostigmine and atropine should be considered for any Hazard Level 2/3 envenoming that presents with symptoms/signs consistent with neurotoxicity (neostigmine 0.03–0.07 mg/kg, i.v. x 1, total dose not to exceed 5 mg; atropine 0.6–1.2 mg i.v. per each 0.5–2.5 mg neostigmine; pediatric dose of neostigmine is the same as the adult dose; pediatric dose of atropine is 0.02 mg/kg for

Fig. 31 The striped sharpnose snake, *Philodryas argentea*. There are no documented bites by this *Philodryas* spp. (Photo copyright to Pedro H. Bernardo)

Fig. 32 The Paraguayan green racer, *Philodryas nattereri*. There are no well-documented bites by this *Philodryas* spp. (Photo copyright to Pedro Bernardo)

each 0.04 mg/kg neostigmine). Atropine administration in patients with bradycardia should immediately precede or be simultaneous with the neostigmine [or other cholinesterase inhibitor].

Hazard Index 3 NFFC: Features of Well-Documented Bites

Available quality evidence and personal experience so far suggest that many NFFC genera occasionally inflict bites that cause mild to moderate local effects, but most of these species have no medical importance. Rarely, protracted bites from the Western hognose snake (*H. nasicus*,

Fig. 33 The Montpellier snake, or hooded malpolon, *Malpolon monspessulanus*, Lamprophiidae, Psammophiinae. This psammophiine is the only NFFC so far to inflict a well-documented envenoming that caused cranial nerve palsy. The victim had placed his fingers into the mouth of the snake and received a protracted bite (Photo copyright to Julian White)

Dipsadidae; see previous sections) [26], the Puerto Rican racer (*Borikenophis* [*Alsophis*] *portoricensis*, Dipsadidae), some larger specimens of *Boiga* spp. (Colubridae, Colubrinae; see Figs. 34, 35, and 36), and *Leptodeira* spp. (cat-eyed snakes, Dipsadidae, Fig. 37) [43] may result in medically significant local effects of moderate severity (e.g., more evidence of higher modified objective pain scores, locally progressive edema, blistering, etc.; see Fig. 38). However, even juvenile specimens of some NFFC species (e.g., false water cobras, *H. gigas*, Dipsadidae; see Fig. 11) can inflict local envenoming with progressive edema and significant local pain [44]. Likewise, *Philodryas patagoniensis* inflicted a handful of well-documented bites that caused mild to moderate local effects, but so far there has been no documented evidence of coagulopathy or any other systemic effect, unlike the widespread ecchymoses that occasionally occur after envenoming by its congener, *P. olfersii* (see Figs. 27 and 28) [1, 3].

It is noteworthy that of the approximately 32 species of *Boiga* spp., only a few well-documented bites have been recorded involving seven taxa. As noted earlier, only *B. irregularis* has been identified as a medically important

Fig. 34 Mangrove or ringed cat eye snake, *Boiga dendrophila* (Colubridae, Colubrinae). The most common *Boiga* spp. in private collections; this species is popular among USA, European, and Asian collectors. Although there are undoubtedly quite a few collectors who have been bitten by this species (including the author), only a few well-documented bites have been reported, and these have consisted of mild-moderate local effects and, rarely, progressive local edema (Photo copyright to Taksa Vasaruchapong)

Fig. 35 The green cat eye snake, *Boiga cyanea* (Colubridae, Colubrinae). Another frequently collected *Boiga* spp.; the very few reported bites have been so far limited to mild local puncture wounds, brief bleeding, and mild local pain. The pictured specimen has notable damage to the rostral scale, a problem that may occur in captive specimens maintained in cages with screens or irregular surfaces (Photo copyright to Taksa Vasaruchapong)

member of the genus. During the last decade, an increased number of *Boiga* spp. has entered the commercial snake trade. Previously, mostly *B. dendrophila* ssp. (mangrove or gold-ringed cat snakes, Fig. 34) and *B. cyanea* (green cat snake, Fig. 35) were imported into the USA,

Western Europe, and some Asian countries, and these species remain the most popular in private collections. To date, there are only a few well-documented reports describing the effects of their bites, which included only mild to moderate local pain, edema (which may be progressive), and erythema [1, 3, 43]. Although there is limited information about the possible effects of bites inflicted by other members of the genus, for reasons discussed earlier, it is important not to prematurely base unproven medical significance of these on murine lethal potency data, nonclinically derived information such as chromatographic profiles, or by using purely in vitro observations obtained from studying their venoms/oral secretions [1, 3, 18].

Fig. 36 The white-spotted cat eye snake, *Boiga drapiezii* (Colubridae, Colubrinae). There are thus far no well-documented bites by this species (Photo copyright to Taksa Vasaruchapong)

Fig. 37 The rain forest cat eye snake, *Leptodeira frenata* (Dipsadidae). There is a documented case of local envenoming by this species. The victim was bitten on the third digit of the right hand and experienced significant local pain, progressive edema that involved the hand and lower forearm, and blistering (see next figure, Photo copyright to Rowland Griffin)

Hazard Index 4 NFFC: Features of Well-Documented Bites

This category contains the majority of NFFC species that have inflicted bites and for which there is some reasonable quality documented evidence. These taxa so far inflict bites that cause mild pain limited to the bite site, some minor bleeding, and mild erythema. Some cause mild local edema, but this may also include the effects in some individuals of local type 1 hypersensitivity. In addition, some medically unqualified anecdotal accounts of “persistent bleeding” after bites by some Hazard Index 4 species are most likely a result of the dentition morphology of many of these snakes, which produce wounds that have irregularly opposed disrupted epidermal planes [3]. These wounds may be disposed to the slowed formation of a fibrin clot, especially if complicated by a protracted grip that often may inflict “raking” wounds that occur during the common withdrawal reaction of a bitten victim. Of course, there is always the possibility that some of these snakes may have venom or other oral products that could contain anticoagulant components that inhibit local clotting, but, to date, there is no evidence of this in any medically qualified report documenting bites, or in bitten patients personally examined, by those species classed here as Hazard Index 4 [1, 3]. Representative Hazard Index 4 genera include the common North American natricids, *Thamnophis* (garter snakes and ribbon

snakes; see Fig. 39; this genus is not to be confused with any of the ten species of African garter snakes (*Elapsoidea* spp., Elapidae), which are all FFC) and *Nerodia* (water snakes). Some clinicians, especially in the Northeastern USA, are occasionally presented with a patient who claims incorrectly to have been bitten by a “cotton-mouth” or “water moccasin,” *Agkistrodon piscivorus*, Viperidae, Crotalinae, because the

snakebite occurred in location nowhere near even extralimital extensions of the *A. piscivorus* range. Although on rare occasions, this is a result of a bite inflicted by an illegal specimen in a private collection or even one released in a location out of the natural range of the species; most of the time, it is a result of misidentification of a *Nerodia* spp. for *A. piscivorus*. Some *Nerodia* spp. readily bite when disturbed and can inflict multiple, painful, bleeding wounds. The colubrine colubrids, *Coluber* (American and Neotropical racers and whip snakes; this now purely New World genus previously contained numerous taxa that have been correctly reassigned to numerous other genera, which especially occur in the Old World), are similarly comprised of approximately 12 species and some of these readily bite when handled or restrained. Resulting wounds typically feature mild pain, local bleeding, erythema.

Many diverse species of snakes are called “racers” or “whip snakes,” and identification must be ascertained as specifically as possible because common names are often shared by numerous taxa. Therefore, it is important to seek the biological/taxonomic history of NFFC snakes involved in any medically significant bite because this can provide information that may aid the management of the afflicted patient.

Fig. 38 Right hand of victim 4.5 days following local envenoming on third digit by the rain forest cat eye snake, *Leptodeira frenata*. The victim experienced rapidly progressive edema, pain, and blistering. Local arthralgia persisted for almost five weeks (Photo copyright to Rowland Griffin)

Fig. 39 The common garter snake, *Thamnophis sirtalis sirtalis* (Natricidae), a species very commonly kept in North American and European collections. Most bites from these snakes produce uncomplicated puncture wounds, variable mild bleeding, and mild pain. There are occasional, rare bites that cause some local edema and erythema (Photo copyright to Christopher E. Smith)

The NFFC Bitten Patient: A Summary of Assessment and Special Considerations*

(*All of the included current information is Evidence Level 3 (see Table 3). Assessment of evidence for diagnosis and management of NFFC envenoming is thus wholly based on case reports; low-powered, small series; respected opinion; and personal experience.)

First Responder/First Aid

Although there are no evidence-based first aid recommendations applicable for NFFC bites, in general, most recommendations for snakebites are still advisable (see Warrell [29], Weinstein et al. [45], Kanaan et al. [46]). However, specific recommendations for NFFC bites/envenoming were evaluated and summarized by Weinstein et al. [1, 3].

The patient should be kept as calm as possible – death from NFFC bites are rare – and the victim should refrain from ambulation to whatever extent possible. Provide fluids (not orally if possible), but withhold food. To whatever extent possible, protect the wound(s) from environmental contamination. Apply a splint to the affected limb, position below heart level. Arrange urgent transport to the nearest medical facility and call ahead. This is especially important in Hazard Level 1 NFFC envenoming because of the aforementioned scarcity of AV for the few species covered, or potentially covered by these products, which are very difficult to procure.

As in any snakebite, all jewelry (hands, wrists, feet, and ankles) should be removed in order to decrease the risk of digital ischemia in the event of progressive edema, and any recent site of dental work, piercing, or tattoos must be carefully scrutinized with any bleeding temporarily managed with carefully applied pressure. Alcohol and any recreational drugs are obviously contraindicated, and, if the patient has any comorbidity, these must be carefully considered along with the continued intake of essential medications (e.g., anticoagulants such as warfarin, or

platelet inhibitors including low-dose aspirin, as well as medications carrying a risk of prerenal effects or bleeding [e.g., NSAIDs], will have to be discontinued until the envenoming has been successfully managed).

If a victim bitten by a Hazard Level 1 NFFC is >2 h transport from a medical facility, application of a pressure pad or use of pressure bandage immobilization (PBI) could be beneficial, although the victim must be informed that this first aid measure is unproven in management of NFFC envenoming and that there is no evidence about the risk vs. benefit of this intervention. It should also be noted that some NFFC bites, including those from Hazard Level 1 species, could cause significant local effects that could be exacerbated by pressure immobilization methods. This is why the important features of the envenoming and associated circumstances must be carefully considered prior to the use of this intervention. Consideration must be given to the likelihood of systemic vs. predominantly local effects, the travel time to hospital, and the availability/ability to rapidly procure AV.

If PBI/pressure pad is performed, it is most important to reasonably occlude local lymphatic drainage, but beware of excessive pressure, as vascular return must not be compromised, and too much local pressure might induce massive ecchymoses/vascular leakage. Although there is no current firm evidence of specific benefit, in an emergent situation, the use of a portable sphygmomanometer (if available) could facilitate this needed balance by maintaining the pressure on the wound site to between 50 and 60 mmHg. Otherwise, this could be roughly approximated by careful application of an elastic bandage or pad with the edge of the application barely allowing a fingertip to slightly lift the edge. The management team should remain cognizant of the possibility on release of the pressure pad or PBI of a sudden release of sequestered venom (“proximal venom surge”). Therefore, serious envenoming managed initially with PBI or pressure pads should be viewed as requiring the prompt availability of AV, whenever possible as clinically indicated, in order to begin AV administration prior to removal of the immobilizing method.

Cryotherapy/ice application, NSAIDs, illicit drugs/alcohol of any kind, constricting ligatures, incision/suction, or any other kind of interference with the wound are contraindicated.

For bites from Hazard Level 2/3 species, the aforementioned pressure pad/PBI should be considered for significant bites by either of the two *Malpolon* spp., or the related *Rhagerhis* (*Scutophis*, Barata et al. [47]; *Malpolon*, Largen and Spawls [48]) *moilensis*, although, as noted previously, only *M. monspessulanus* has inflicted a single well-documented neurotoxic envenoming.

For bites from Hazard Level 4 species for which there is significant documented evidence, most commonly all that is required is thorough irrigation of the wound (mild soap and water are all that is needed) and basic wound dressing. In the event of more medically significant bites from Level 4 species, the victim should receive comprehensive review, as noted for the more medically important, higher-risk index taxa.

Important Considerations

See previous section entitled, “[Important Features of Management of Medically Significant Hazard Index 1 Envenoming](#),” as well as the section “Important Features of Envenoming” for Hazard Levels 2/3 and 4.

Any significant Hazard Index 1 envenoming, or progressive Index 2/3 envenoming, should prompt consultation with an experienced clinical toxinologist or medical toxicologist familiar with snakebite envenoming.

Indications for Antivenom

As described above, the only AVs available for any NFFC envenoming are against D. typus and R. tigrinus. AV against R. tigrinus probably has paraspecific neutralizing activity for R. subminiatus and, possibly, B. ceylonensis venom and should be used whenever possible in any case of life-threatening envenoming by these

two species. To date, there is only animal experimental data-based evidence of the paraspecificity for *R. subminiatus* venom, and all well-documented envenoming by this taxon have been successfully managed with either replacement therapy (see ahead) or have simply been observed with subsequent spontaneous resolution. As mentioned earlier, possible paraspecificity of this AV against *B. ceylonensis* venom is hypothetically based on the close relationship between these genera and the similarity of the single well-documented serious envenoming inflicted by this species with that of *R. tigrinus* and *R. subminiatus*.

It is essential to note that there is no AV for any other NFFC species, including the Hazard Level 1, *Thelotornis* spp., and no evidence of any efficacy of any other AV for bites by any other NFFC taxa. This includes the known medically important two taxa of *Philodryas* (*P. olfersii* and *P. patagoniensis*) for which there are a few data suggesting some in vitro neutralization of venom hemorrhagic activity, but for which there is no evidence of clinical efficacy of any AV. Also, so far there is no well-documented envenoming by these species that would necessitate provision of AV even if an effective preparation were available.

Therefore, aside from the Hazard Level 1 species specifically described above, no AV should be given for any other NFFC.

Efforts to obtain AV must begin early, as the procurement of these scarce AV is notoriously difficult (and markedly expensive). The indications for AV in Hazard Level 1 envenoming include:

Evidence of coagulopathy including active bleeding (gingiva, persistent bleeding from wound site(s), recent surgical sites, recently shaved skin, persistent epistaxis, lacerations/injuries, tattoos, hemorrhoids, or piercings, hematemesis, hematuria, etc.).

Abnormal lab tests indicative of serious envenoming (abnormal PT/aPTT/INR), thrombocytopenia or trend of decreasing platelet counts; intravascular hemolysis, abnormal renal function tests, etc. Abnormal tests can include >20 min whole blood clotting assay (in the circumstance of unavailability of

instrumented laboratory testing), although this test may have poor sensitivity/specificity under certain circumstances and its accuracy for clinical diagnosis in NFFC Hazard Level 1 envenoming is so far undocumented.

Clinical evidence of serious systemic envenoming as noted in results of physical examination or vital observations such as an isolated systolic hypotension, diaphoresis and tachycardia (e.g., early signs of impending shock), the aforementioned signs of active bleeding, etc.

Any patient with cardiovascular comorbidities including history of stroke or myocardial infarct must be closely monitored (with telemetry whenever possible), a baseline electrocardiogram obtained, and, when indicated, cardiac enzymes serially monitored before and after receiving AV.

Provision of antivenom

- A. Large-gauge IV access for fluids; provide fluid bolus and repeat as clinically indicated.
- B. Anaphylaxis protocol with crash cart must be in place *before* the administration of AV.

Antivenom dosing and administration:

- For *D. typus* envenoming, dilute one vial (10 mL) of *D. typus* AV in 250 mL saline, and infuse intravenously initially 60–100 mL per hour. Carefully monitor patient for any signs of adverse reactions (e.g., hypotension, maculopapular rash [often first appears on trunk and centrifugally spreads], bronchospasm, fever, etc.). If there is no adverse reaction, administer the entire dose within 30 min.
- For *R. tigrinus*, *R. subminiatus*, or *B. ceylonensis* envenoming, reconstitute one vial of lyophilized *R. tigrinus* AV in 10 mL saline (*do not shake or agitate*; only very gently swirl to facilitate optimum dissolution), and dilute in 250 mL saline. Administer and monitor the patient as noted for provision of *D. typus* AV.
- If possible, obtain an additional vial in case a larger dose is required for particularly severe envenoming. Most well-documented cases

have required only a single vial of either AV, but there have been several patients severely envenomed by *D. typus* or *R. tigrinus* that have required two or (rarely) more vials. Both AVs have shown clinical efficacy for up to 5 days after the initial presentation.

- As previously described, so far there has been only a single well-documented neurotoxic envenoming from a NFFC bite (from *M. monspessulanus*), although the envenomed patient experienced only transient cranial nerve palsy without any evidence of descending paresis; the possibility of a more severe paralytic envenoming by this taxon (or other related or yet other medically uncharacterized species) must be considered. Therefore, even though intubation and ventilation have so far been unnecessary in management of a neurotoxic NFFC envenoming, the lack of any AV for NFFC species (so far only this single psammophine lampprophiid) likely to inflict such an envenoming suggests that in the event of descending paralysis after an envenoming by *M. monspessulanus*, intubation and ventilation may be necessary in some patients.
- Any patient seriously envenomed by a Hazard Level 1 species and those with less severe envenoming but with cardiovascular, hematological, and/or oncological comorbidities should be admitted to the intensive care unit.
- Wound care and supportive management (e.g., fluid resuscitation, nonsedating analgesia) should be promptly provided and the clinical response to treatment carefully monitored.

Special Populations (Seriously Envenomed Pediatric and Pregnant Patients)

- Pediatric patients should receive the same antivenom dose as an adult, and severely envenomed children may require larger amounts.
- Pregnant patients should also receive the same antivenom dose and should have closely

scrutinized cardiotocography (CTG, fetal heartbeat and uterine contraction monitoring) and serial review by an obstetrician, preferably with experience with high-risk patients. It is relevant to note that there has been little formal investigation of the pharmacokinetics of antivenom when provided to pregnant patients. Although studies of most pharmaceuticals provided to pregnant patients have shown that bioavailability remains essentially unaltered, it is unclear if this also applies to antivenom. It is possible that through changes in the volume of distribution and clearance, pregnancy might cause an increase or decrease in the terminal elimination half-life of pharmaceuticals that have not been thoroughly studied in pregnant women [49]. This could include antivenom, and thus some seriously envenomed pregnant patients may require larger doses of antivenom. It is noteworthy that in a pharmacokinetics study of three monospecific antivenoms against Malayan pit viper (*Calloselasma rhodostoma*), the total apparent volume of distribution for each antivenom was 1.5–3 times larger than that of the central compartment [50]. This suggests the occurrence of significant tissue distribution in addition to complex formation, and this could be a factor of increased significance for some envenomed pregnant patients especially in the second and third trimesters.

Indications for and Concerns Regarding Replacement Therapy

Some patients envenomed by Hazard Index 1 species have on occasion been provided with FFP, cryoprecipitate, PRBC, platelets, and/or fibrinogen.

Fresh Frozen Plasma and Cryoprecipitate

The use of these products in life-threatening envenoming by Hazard Level 1 species has been critically reviewed with the conclusion

that there is so far insufficient evidence to recommend inclusion of FFP, cryoprecipitate, or fibrinogen in the standard management of envenoming by these taxa because there is no clear benefit, and possibly increased risk, associated with their use [3]. Some patients with life-threatening envenoming by Hazard Index 1 NFFC species (particularly by *R. subminiatus* and *R. tigrinus*) have been given prodigious amounts of FFP and/or cryoprecipitate [3]. However, there may be patients who present with notably increased bleeding/massive hemorrhage risk, and judicious use of these (with AV whenever possible; see ahead) *may* be clinically justified. In most snake venom-induced coagulopathy (from envenoming by FFP and NFFC), fibrinogen levels are often undetectable for some 12–24 h post envenoming but usually become detectable 24–36 h post envenoming [51–53]. However, some hypofibrinogenemic patients may require cryoprecipitate if fibrinogen is <100 mg/dL (3 μ mol/L) and/or there is clinically significant hemorrhage [54].

The use of these products in the setting of life-threatening snake venom-induced coagulopathy raise concerns about adding substrate for the continued action of procoagulant toxins, e.g., “throwing fuel on the fire,” as well as increased risk of exposure to blood-borne pathogens and bacterial contamination [3, 54]. As noted above, most well-documented cases of Hazard Index 1 NFFC envenoming that have included provision of these products have demonstrated no clear therapeutic benefit from these interventions. However, some patients envenomed by *R. subminiatus* and *T. capensis* have recovered after being managed with replacement therapy including, in some cases, FFP and/or cryoprecipitate [3]. It remains unclear whether these patients clinically benefitted from this therapy or rather had simply received self-limiting, non-life-threatening envenoming.

As previously emphasized, management of life-threatening envenoming by *D. typus*, *R. tigrinus*, *R. subminiatus*, and *B. ceylonensis* should whenever possible include the central use of appropriate AV for these species.

Although there is little quality evidence supporting the provision of FFP or cryoprecipitate in consumptive coagulopathic envenoming, one group of investigators have suggested that the provision of FFP may provide some benefit in the management of defibrinating coagulopathic envenoming from an Australian elapid (*Pseudonaja textilis*, Eastern or common brown snake) provided it is given with AV and within 4 h of the envenoming [55]. Further careful study of this question is desirable.

Packed Red Blood Cells

Packed red blood cells should be provided if the patient develops significant anemia, and the threshold for transfusion should not strictly conform to standard protocol, but should be determined by the individual patient's cardiovascular, perfusion, respiratory, and oxygenation status. Some patients with serious Hazard Index 1 envenoming have required >10 units of PRBC.

Platelets

Likewise, platelet infusions should be provided as indicated by clinical need and individual bleeding risk of a given patient. There is no uniform consensus on platelet transfusion thresholds, but patients who develop thrombocytopenia often show a rapid reduction in platelet levels that may remain below 50,000/mm (normal adult range: 150,000–400,000) [3] for as long as a week or even more [53]. Platelet infusions rarely shorten or notably improve the duration of snake venom-induced thrombocytopenia [3], but the provision of infused platelets is necessary if the patient spontaneously bleeds or has an increased risk of clinically significant bleeding. The threshold for prophylactic provision of platelets varies on circumstances and patient morbidities and can range between 5,000 and 100,000/mm [3] [56, 57]. Patients with marked and persistent thrombocytopenia require frequent neurological monitoring because these patients are at increased risk for a fatal outcome. Non-contrast

computerized tomographic study of the head should be performed in any patient with altered sensorium in the setting of a severe coagulopathic envenoming because of the increased risk of central nervous system bleeding. A well-known and tragic example of this is the hemorrhagic infarct that caused the death of the esteemed, historically important herpetologist, Robert F.W. Mertens, after severe envenoming from a *T. kirtlandii* [58].

General Treatment Considerations

Serial assessment of INR, renal function, and platelets is essential (e.g., reversal of prolonged INR is sufficient to withhold any additional AV that might be available, but INR must be monitored for at least 3–4 days after severe envenoming, and sometimes longer) (Table 3). Serious envenoming by any of the Hazard 1 Index taxa requires ICU admission, close monitoring, and extended serial laboratory assessments.

Compartment syndrome requiring surgical intervention is a rare complication of some (mainly viperid) snakebite envenoming that may be confused with direct venom-induced muscle necrosis or myositis. One patient with local envenoming from a Hazard Level 3 NFFC species (*Philodryas viridissima* Wallach et al. 2014] *viridissimus*; green palm snake; common green racer, Dipsadidae) was probably subjected to an unnecessary fasciotomy because of the aforementioned confusion [3]. In addition to serial clinical evaluation, a Stryker[®], wick catheter, or other intracompartmental pressure measurement >30 mmHg is required for diagnosis of any suspected compartment syndrome. If this equipment is unavailable, even a bedside Doppler measurement may help resolve clinical suspicion. In the rare event that envenoming-induced compartment syndrome is present, urgent surgical consultation is required. It must be noted that the pressure threshold for defining compartment syndrome varies among different surgical specialties. For instance, several vascular and orthopedic surgeons informally indicated that they, respectively, used intracompartmental

pressures ranging between 30 and 35 mmHg, or 35 – >40 mmHg, as thresholds for diagnosing compartment syndrome [53].

Additional treatments may include non-sedating analgesia, dialysis for established renal failure (hemodialysis is superior to peritoneal dialysis), aggressive fluid resuscitation, and respiratory support, as indicated.

After administration of antivenom, a short, nontapered course of prednisone (40–60 mg daily for 5 days) should be given to decrease the incidence of type III immune complex disease (grade III recommendation).

Meticulous wound care and tetanus prophylaxis should be provided as indicated. Aggressive wound care is especially important in the event of non-sterile interference with the wound (e.g., inappropriate first aid, exposure to saprophytic or marine organisms, etc.). Antibiotics are indicated only if evidence of infection is present.

All patients with serious envenomation must be counseled about the risk of antivenom anaphylaxis, immune complex disease, and possible loss of function, regardless of treatment effectiveness.

Discharge and Follow-Up

Patients who have had life-threatening Hazard Index 1 envenoming must have had several serial sets of normal laboratory investigations and be clinically stable. Patients with comorbid renal and/or cardiovascular disease (including resistant essential hypertension) who are recovering from a life-threatening envenoming should be very carefully assessed before being discharged. A longer inpatient management period should be expected for these patients. Those with less serious local envenoming by Hazard Index 2–4 species should have an arranged follow-up appointment with their primary care physician, as well as arrangements for meticulous wound care when clinically indicated.

Any patient with evidence of an acute kidney injury (AKI) or cardiovascular insult must have timely respective follow up with a nephrologist or cardiologist.

Long-Term Considerations/Prognosis

Most patients envenomed by NFFC have a complete, uncomplicated recovery. However, patients seriously envenomed by Hazard Index 1 species who had AKI may experience some association of this injury with long-term mortality and morbidity, as has been shown for AKI with varied etiologies [59, 60]. Likewise, any patient with cardiovascular complications including cerebrovascular infarct may have a guarded prognosis depending on the extent of injury, age, and comorbidities. Careful follow-up of these patients is mandatory.

Legal Pitfalls

All patients, including those with significant local envenoming, should be carefully counseled about possible loss of function, delayed and incomplete healing, and possible loss of local sensation (especially after significant and prolonged digital edema) even after correct treatment. Any patient or their legal proxy must be informed of the risks and benefits of AV, as well as the likely significant delay in procuring AV as needed for Hazard Index 1 envenoming. They should also be counseled about the possibility of failed therapy even with the provision of timely and effective treatment and should be informed if these products have not been specifically approved by the relevant regulatory agency. The lack of high-quality evidence supporting replacement therapy should be clarified especially when it is deemed necessary for serious envenoming by *Thelotornis* spp. because it is the sole management strategy for envenoming by these snakes, as there is no AV.

Similarly, in the event of treatment of life-threatening envenoming by *R. subminiatus* or *B. ceylonensis* with anti-*R. tigrinus* AV, the patient or legal proxy should be carefully informed about the lack of any evidence for clinically effective paraspecific neutralization of the venoms of these species by this AV.

The American Association of Poison Control Centers reported 90 coral snake bites in 2014 [1]; 51 (57%) of these were reported from Florida [2]. Of these, three patients required ventilator support or airway protection either due to a late presentation or shortage of antivenom. In 2006, a death occurred in Florida in a 29-year-old male who did not seek medical attention. Coral snakes belong to the family *Elapidae* (Fig. 1). Among the elapids are cobras, mambas, sea snakes, and corals. Coral snakes comprise three genera: *Leptomicrurus*, *Micrurus*, and *Micruroides*. *Micrurus* and *Micruroides* are the only endemic North American elapids [3]. *Micrurus fulvius* has five subspecies; *M. fulvius fulvius* (Eastern coral snake) and, to a lesser extent, *M. fulvius tenere* (Texas coral snake) are the most medically important. No reports exist of significant human toxicity due to *Micruroides euryxanthus* (Sonoran coral snake).

The Eastern coral snake, small in comparison to the pit vipers, grows to 129.5 cm (51 in.) [4] and has a black, rounded head with a flat snout and rounded eyes (Fig. 2). The concentric banding pattern with black, yellow, red, yellow gives rise to the mnemonic: “red on yellow, kill a fellow; red on black, venom lack.” Several nonvenomous snakes in North America mimic the coral snake, most notably the king snake. Coral snakes should be distinguished easily from these if a specimen is available for examination; however, misidentification, even by professionals at a pet store, has led to envenomation [5]. Occasionally, albino

snakes and phenotypic variations that break the rule are found in the wild.

M. fulvius is solitary, except when breeding. It can be aggressive toward its own species, but it is otherwise mild-mannered and does not attack humans. The defensive posture of the coral snake often includes a popping sound made with the tail. This behavior is thought to be an evolutionary tactic, used to confuse predators. The first description of a coral snake bite by True [6] in 1883 expressed surprise that the snake did not sting with its tail. As with pit viper envenomation, most coral snake bites are the result of the animal defending itself.

Venom Biochemistry and Pathophysiology

The chemical components of *Micrurus* toxin still are not well understood in comparison to Old World elapids. The dry venom consists of 75% protein [7], representing a complex mixture of enzymes and nonenzymatic toxins. Recently, high-throughput transcriptomic sequencing of the venom gland transcriptome of *Micrurus fulvius* has been performed [8]. Approximately 86% of the venom gland genome identified as toxin were identified as unique sequences for phospholipase A_2 and three-finger toxins. Together the two toxins account for the majority of coral snake venom's clinical neurotoxicity. Phospholipase A_2 , in particular, is responsible for neurotoxicity both presynaptically and postsynaptically, as well as myotoxicity, cardiotoxicity, hemolytic activity, and anticoagulant activity [9]. Zinc-dependent anticholinesterase may be partially responsible for effects on neuromuscular transmission at the nicotinic endplate resulting in curare-like effects [10, 11]. The long-term effects of coral snake envenomation, occasionally lasting up to 6 weeks, are most consistent with a presynaptic toxin and destruction of the neuronal cell. This is further supported by the clinical observation that toxicity, once established, cannot be reversed even by tripling the standard dose of antivenom.

Three-Finger Toxins, named for the appearance of their chemical structure postsynaptically inhibit acetylcholine at the nicotinic receptor or the neuromuscular endplate [12]. Long-chain neurotoxins are similar to three-finger toxins with the addition of side chains. Metalloproteinases, a hemorrhagic toxin found in *Crotalinae*, have less clear significance in the corals. Kunitz proteins, the fifth most abundant toxin found in the *Micrurus* genome, are an inhibitor of serine proteases and calcium and potassium ion channels. Hyaluronidase, L-amino acid oxidase, phosphatases, phosphodiesterases, adenosine triphosphatase, and deoxynucleoside phosphatase (DNPase) have been described [13–17]. Other venom components include lipids, carbohydrates, riboflavin, zinc, calcium, magnesium, and potassium.

Coral snakes are proteroglyphodonts, having two anteriorly located fixed maxillary teeth, or fangs, attached to venom apparatus. The amount of venom injected into a victim is difficult to determine; however, this seems to be controllable by the coral snake [18]. The average amount of venom available varies from species to species and is proportionate to the size of the snake. The average yield of venom obtained from milking snakes is 12–20 mg for *M. fulvius* and only 6 mg from *M. euryxanthus* [15, 18, 19].

The average median lethal dose for 18-g mice is reported to be 9 μ g [20]. Given the average yield per snake, it is apparent that a bite from *M. fulvius* easily could be fatal to a human if the weight-adjusted median lethal dose is similar. However, there is a considerable difference in the LD₅₀ even among different species of mice and extrapolation to humans may not be possible.

Clinical Presentation

Fang marks are the most frequent initial clinical finding. Fang marks may be multiple, may appear as an abrasion, or may be absent. The ability to express a small drop of blood may be present in 85% of patients [21]. However, envenomations have occurred with minimal local signs

[22]. The practice of injecting lidocaine or saline into the bite site to observe expression of fluid from the fang marks has little, if any, clinical value. It has been stated that these snakes need to chew venom into the wound to inject sufficient venom [21]. Patients occasionally report a “Velcro-like” sensation when removing a coral snake, and this is believed to correlate with the subsequent development of toxicity. However, this chewing action may not be necessary for envenomation. Only a few patients in the Florida Poison Information Center database have given a history of the snake “holding on” during a bite.

Local swelling occurs in approximately one-third of patients [21] and is typically mild compared with pit viper envenomation. The lack of local tissue injury often leads medical personnel to underestimate the severity of the injury, particularly if the patient is intoxicated. Localized pain at the bite site is common, as are paresthesias.

The mean time to onset of symptoms is 140 min; however, toxicity may be delayed 13 h [18]. Most patients who present to the hospital are asymptomatic. Asymptomatic patients, if adequately treated with antivenom before the onset of symptoms, do not go on to develop toxicity. Nausea and vomiting occur in approximately 25% of patients [21]. One patient described the following symptom to the author, “It was like thousands of bees buzzing in my ears.”

Cranial nerves are affected early, with the patient experiencing diplopia, ptosis, dysarthria, difficulty swallowing, and depressed gag reflex. Aspiration pneumonia is a frequent complication, particularly when early, aggressive airway protection is not maintained. Paralysis of the muscles of respiration and respiratory failure may follow, with subsequent paralysis of skeletal muscles, which is preceded by muscle fasciculations in only about 5% of cases [21]. Whether paralysis proceeds in an ascending or descending fashion has not yet been described. Although paralysis in an untreated patient may last as long as 2 months, long-term sequelae have not been observed. Mental status most often remains normal. Some patients with incomplete paralysis have been able to communicate through writing.

Cardiovascular toxicity has been shown in dog models with lethal doses of venom from *M. fulvius fulvius* [23]. No such toxicity has been reported in humans. Hemolytic effects on in vitro human red blood cells have been shown, but this does not seem to be clinically relevant for patients [16].

Diagnosis

The diagnosis usually is evident from the history given by the patient. In the series by Kitchens and Van Mierop [21], nine patients who intentionally handled the snake believed they were handling a king snake. In one report of envenomation, the patient was told by a local pet shop that a snake was a king snake [5]. Occasionally a patient, often intoxicated, gives a history of having been bitten by an unknown brightly colored snake. It is often difficult to determine if envenomation has occurred. If no snake is available for identification, the risks of antivenom administration must be weighed against the risks of untreated envenomation. Experimentally, and in rare clinical circumstances, enzyme-linked immunosorbent assay has been performed on the blood of unconscious patients to diagnose coral snake envenomation. This test is not routinely commercially available, however, and can be expensive. Enzyme-linked immunosorbent assay is not indicated in cases in which the diagnosis already is known. Treatment of suspected envenomation should not be delayed for laboratory work of any kind. Routine laboratory studies may be required before intensive care unit admission per protocol and custom in many hospitals. The laboratory is not helpful, however, in making a specific diagnosis because neither coagulopathy nor rhabdomyolysis occurs in routine coral snake envenomation. A chest x-ray should be obtained, particularly if aspiration is suspected. Because paralysis lasts several days to months; arterial access is preferable for multiple arterial blood gas measurements.

Treatment

Indications for ICU Admission in Poisoning by North American Coral Snakes and Related Elapids

1. All patients with strong suspicion of coral snake bite should be treated or monitored in the intensive care unit for the first 24 h.
2. Symptomatic patients should remain intubated in a critical care unit until a patent airway can be maintained by the patient.
3. Patients who have had anaphylactic/anaphylactoid symptoms from antivenom should be admitted to the intensive care unit.
4. Prior history of administration of antivenom or history or allergy to antivenom does not contraindicate administration of antivenom. The risk-benefits should be weighed preferably with the input of a clinical toxicology consultant.

Early and aggressive airway management and ventilatory support are mandatory because aspiration pneumonia is a frequent early complication. The supportive treatment of symptomatic patients mirrors the treatment of Guillain-Barré syndrome or botulism. The patient may have complete or partial paralysis of skeletal musculature but typically has normal mental status. It is important that the patient's psychological needs are met in addition to ventilatory and nutritional support.

Antivenom

The mainstay of treatment of *M. fulvius* is North American Coral Snake Antivenin (Wyeth Laboratories, Marietta, PA) (Grade II-3 evidence). This antivenom is produced by progressive immunization of horses and subsequent harvest of immune serum, presumptively rich in IgG. The immune horse serum is lyophilized for longer storage life. Because neurotoxic effects from *M. fulvius fulvius*, when manifest, are largely irreversible

by antivenom, it is important to administer antivenom even when the diagnosis is suspected but not confirmed (Grade II-3 evidence). The Florida Poison Centers performed a retrospective observational study to determine if a “wait and see” approach to the administration of antivenom could be used in asymptomatic patients. However, due to the retrospective nature of the study, this cannot be recommended [24].

North American Coral Snake Antivenin was licensed in 1967. Until that time, it was estimated that the mortality from untreated Coral Snake bite was 10% [4]. The effectiveness of North American Coral Snake Antivenin is virtually 100% effective if given prior to the onset of effects as the development of toxicity after administration of antivenom is unheard of. At the time of discontinuation of antivenom production in 2003, Wyeth Laboratories produced a 5-year supply of antivenom to allow the transition to a newer product. The existing lots were to expire in 2008. In 2009, Pfizer purchased Wyeth as a wholly owned subsidiary. But, to date, no new antivenom has been produced. The US Food and Drug Administration has allowed for the extension of two lots of Wyeth antivenom, both of which had the original expiration date of October 2008. Lot 4030026 was renewed annually from October 2009 until October 2014. Lot 4030024 was first renewed in April 2014 but has been extended twice since that time.

For asymptomatic patients with clear evidence of significant coral snake bite, a minimum of 3–5 vials of North American Coral Snake Antivenin is considered to be appropriate (Grade III evidence). The Wyeth *Micrurus* antivenom package insert recommends consideration of a repeat course of 3 to 5 vials; however, the indications for repeat treatment are left to the discretion of the practitioner. Asymptomatic patients who have received five vials of coral snake antivenom have not been described to display subsequent signs of envenomation, and the administration of five vials seems to be adequate for this population.

For patients develop clinical effects before or during the administration of antivenom, the author recommends administering 3–5 additional vials of antivenom. Although additional higher doses of

antivenom have not been shown to reverse the effects of coral snake envenomation, application of the higher end of the recommended therapeutic dosing range seems prudent.

The package of Wyeth *Micrurus* antivenom contains two vials: lyophilized antivenom with 0.25% phenol and 0.005% thimerosal and 10 mL of bacteriostatic water with phenylmercuric nitrate (1:100,000) as a diluent. The powdered protein contained in the lyophilized antivenom vial can be reconstituted either by using the diluent that comes in the package or by filling the vials with 10 mL of 5% dextrose in water (D₅W) or normal saline from an intravenous bag. The latter process makes antivenom reconstitution and placement of the contents of the vials back into the intravenous bag easier and more efficient. The vials are warmed gradually and rolled gently (not shaken, as this may cause foaming and also denature the proteins) between the hands until all powder has gone into solution. Care should be taken to ensure that all particles of the lyophilized powder are dissolved completely (suspension in foam causes powder to catch in filters). This process typically takes 15–30 min.

I place 3–5 vials of antivenom in a weight-appropriate volume of diluent (250–500 mL of either D₅W or normal saline is appropriate for adults). An infusion is begun through a micropore filter at a rate of about 3 mL/h. The rate may be doubled every 2 min as tolerated. The initial goal of therapy should be the administration of six vials over 1–1.5 h.

Pretreatment with antihistamines, steroids, or antibiotics is unnecessary for most patients. Caution should be taken with patients with a prior history of allergic reaction to horse serum or prior administration of horse serum-based antivenom. Although antivenom administration is not contraindicated in these patients, the risk-to-benefit ratio must be assessed. If therapy is deemed necessary in these patients, pretreatment with H₁ and H₂ antagonists and corticosteroids is indicated (Grade III recommendation). Tetanus immunization should be updated if necessary. Because animal sera contain foreign protein, immediate hypersensitivity reactions are common. Experience with

Wyeth Laboratories (Crotalidae) Antivenin Polyvalent, another equine-derived antivenom revealed the incidence of anaphylactic, anaphylactoid, and serum sickness to be 83% [25]. Serum sickness (type III hypersensitivity) is a delayed (days to weeks) manifestation of immune complex formation. Adverse reactions to antivenoms are described in ► Chaps. 116, “Overview of Scorpion Envenoming,” and ► 151, “Immunotherapy.”

During the administration of antivenom, I recommend observing the patient vigilantly for type I, or immediate, hypersensitivity reactions. Hypersensitivity reactions range from a mild rash to acute bronchospasm or anaphylactic shock or both. This may be true anaphylaxis or, more commonly, a nonspecific anaphylactoid reaction (i.e., not IgE mediated). If there is concern about the possibility of a reaction, it is prudent to prepare an intravenous epinephrine infusion (1 mg in 250 mL of D₅W), which could be started immediately if necessary. The infusion rate, if needed, is typically 0.1–1.0 µg/kg/min for adults or 0.05–1.0 µg/kg/min for children. The first step in the treatment of acute allergic phenomena is to stop the antivenom infusion. Fluid administration and Trendelenburg positioning may be helpful in blood pressure support. The patient should be given weight-appropriate doses of diphenhydramine and an H₂-blocker, such as cimetidine or ranitidine. Intravenous methylprednisolone may not be immediately helpful but may have a role if restarting the antivenom infusion is considered. β₂-Adrenergic agonists should be administered if necessary for the treatment of bronchospasm. Epinephrine should be given for hypotension or bronchospasm. Serum sickness, a type III (or immune complex) hypersensitivity reaction, occurs in many patients 3–21 days after antivenom administration (most commonly between days 7 and 14) [25]. The risk of serum sickness is related to the number of vials of antivenom given (i.e., total foreign protein load). Serum sickness typically presents as a flulike illness, arthralgias, and rash. More severe cases with glomerulonephritis and pericarditis have been reported. Most cases however respond well to antihistamines and a course of prednisone. Fear of serum sickness should not be used as an argument to avoid the use of antivenom.

A Costa Rican polyvalent anti-coral antivenom (Instituto Clodomiro Picado, Universidad de Costa Rica) exists for treatment of coral snake envenomation in Central and South America. There is no literature on its effectiveness in North American coral snake bites although activity against venom from *Micrurus nigrocinctus*, *Micrurus carinicaudus*, *Micrurus fulvius fulvius*, and *M. fulvius tenere* is reported. It is derived from horse serum and precipitated using caprylic acid.

An F(ab')₂ Coralmyn (Instituto Bioclon, Mexico) exists for treatment of coral snake envenomation in Central and South America. There is no literature on its effectiveness in North American coral snake bites, although both report activity against venom from *Micrurus fulvius fulvius* and *M. fulvius tenere*. It was developed with venom from *Micrurus nigrocinctus*. It is prepared by immunizing sheep and digesting the IgG molecule with pepsin. The result of splitting the molecule is a 100,000 molecular weight F(ab')₂ and a 50,000 molecular weight Fc fraction. The Fc fragment, which is responsible for binding to and triggering degranulation of mast cells and activating the complement cascade, is removed. F(ab')₂ has theoretical, but untested, advantages over Fab and whole IgG. The product is believed to be less allergenic to humans than crude IgG preparations due to the absence of albumin, other foreign proteins, and Fc fragment. The allosteric configuration of F(ab')₂ is closer to that of IgG and may bind to antigen more tightly than Fab. There is concern that Fab may be filtered by the glomerulus and has a short biologic half-life; this is less likely to occur with F(ab')₂ given the latter's greater molecular weight. This F(ab')₂ antivenom has been used successfully for the treatment of coral snake bite in Mexico and Central and South America. Though no US clinical trials have been performed, it has been shown to be equally effective at neutralizing venom from *M. fulvius tenere* and *M. fulvius fulvius* in mice. Neither the Instituto Bioclon antivenom nor the Costa Rican polyvalent anti-coral antivenom is commercially available in North America. They occasionally may be found in local zoos and theme parks that handle poisonous animals or through the Miami-

Dade Fire Rescue Antivenom Unit [26]. An ovine Fab antivenom has been developed from *M. fulvius fulvius* but has not been tested in humans [27].

Criteria for ICU Discharge in Poisoning by North American Coral Snakes and Related Elapids

1. Asymptomatic patients may be discharged after 24 h of observation from the time of the bite.
2. Symptomatic patients may be discharged when adequate airway and ventilation can be maintained.
3. Symptomatic patients should have an absence of progression of symptoms for 24 h before discharge.

It may be possible to use antivenoms from Central and South America should a shortage of North American Coral Snake Antivenom exist. Cross-neutralization of *M. fulvius fulvius* venom by anti-*Micrurus carinicauda dumerilii* serum has been shown [28]. General considerations regarding immunotherapy are discussed in detail in ► Chap. 151, “Immunotherapy.”

Currently, patients are being enrolled in a clinical trial for an F(ab')₂ in Florida (INA2013).

Neostigmine was used to improve symptoms in a single case report of a 35-year-old patient with suspected envenomation from *Micrurus* [29]. No experience with neostigmine exists for treatment of North American coral snakes, although it has been used for other elapids whose venoms exert postsynaptic neurotoxic effects on the neuromuscular junction [30]. The irreversibility of symptoms through the destruction of neurons by a presynaptic toxin would suggest that neostigmine might be, at best, a temporizing measure.

Special Populations

Pediatric Patients

The antivenom dosage for children should not be altered. Antivenom contains immunoglobulins, which have an affinity for venom. The amount of

venom to be bound by antivenom, not the weight of the patient, is the determining factor for the effective dose of antivenom. However, reducing the total fluid volume may be reasonable to avoid fluid overload. The rate of administration of antivenom may need to be slowed if the volume is reduced resulting in a more concentrated solution.

Pregnant Patients

There is a paucity of literature on coral snake bite in pregnancy, probably because pregnant women are less likely to be exposed to the risk of envenomation. In one Brazilian study, three of eight pregnant snakebite victims developed premature contractions, threatened abortion, fetal arrhythmia, and intrauterine fetal demise [31]. The use of antivenom in pregnancy has been inferred from the literature on other envenomations. Wyeth Laboratories *Micrurus* antivenin carries a US Food and Drug Administration pregnancy C category. Although no relevant human studies exist, the risk-to-benefit ratio must be weighed [32]. Because of the possible adverse fetal effects of maternal envenomation, the indications to use antivenom in pregnant patients should be the same as for nonpregnant patients (Grade III recommendation).

Patients with Late Presentation

A dilemma often exists with asymptomatic patients who have presented to the hospital many hours after a presumed coral snake bite. Although the likelihood of a significant envenomation decreases for a patient 12 h from the time of the bite, the consequence of the delay in treatment may be a missed opportunity to prevent a prolonged hospital course, one that often is fraught with complications. In these instances, it is usually best to err on the side of caution by giving antivenom. Expectant observation also is an acceptable option. The risks and benefits must be discussed in detail with the patient. Consultation with a clinical toxicologist is highly recommended in this situation.

Common Errors in Treatment of Poisoning by North American Coral Snakes and Related Elapids

Delay in protecting the patient's airway
 Undertreatment of pediatric patients with antivenom

Approaching the coral snake victim similar to the victim of crotaline snakebite (i.e., using soft tissue swelling or laboratory findings as an indicator for therapy)

Using *Crotalinae* or other antivenom for treatment of coral snake

Key Points in Poisoning by North American Coral Snakes and Related Elapids

1. Victims of a coral snake bite present with little, if any, local symptoms.
2. Patients with known or suspected coral snake bite should be treated before the onset of symptoms.
3. Aggressive, early airway protection in patients with evolving symptoms avoids the common complication of aspiration pneumonia.
4. There is no role for steroids (except in the treatment of reactions to antivenom).
5. There is no role for prophylactic antibiotics.
6. Tetanus immunization should be updated, if needed.
7. Untreated patients with full-blown toxicity have paralysis, not coma, and appropriate psychological considerations for a conscious but paralyzed patient should be maintained.

North America is home to more than 30 species and subspecies of venomous snakes (Table 1). These fall within two snake families: the Viperidae and Elapidae. The majority of human envenomations occurring in the United States (US) result from bites by members of the subfamily of Viperids known as Crotalinae. The Crotalinae, alternately referred to as crotaline snakes, crotalids, New World vipers, or pit vipers, are comprised of snakes from the genera *Crotalus* and *Sistrurus* (rattlesnakes) and *Agkistrodon* (cottonmouths and copperheads). A minority of native venomous snakebites are due to coral snakes, which are discussed in ► [Chap. 125, “North American Coral Snakes and Related Elapids.”](#)

Pit vipers possess heat-sensing organs, or “pits,” located posterior to each nostril which function in locating prey. Other characteristics that distinguish pit vipers include a triangular-shaped head and elliptical pupil. Pit vipers, like all Viperidae, possess mobile fangs located in the front of the mouth that can be rotated forward during a strike and retracted quickly back into the mouth. The paired fangs deliver venom via venom ducts, from paired specific venom glands located towards the posterior part of the head, laterally. In addition to these characteristics, rattlesnakes also possess a modified scale structure, the “rattle,” which is an appendage at the base of the tail that, when shaken, signals a warning to predators. However, the rattle may be absent in very young rattlesnakes or it may be lost. Even

Table 1 US Crotalinae – medically important species and selected subspecies

Genus/Species	Common name	General range in U.S.
<i>Crotalus</i>	Rattlesnakes	
<i>C. adamanteus</i>	Eastern diamondback rattlesnake	Southeastern
<i>C. atrox</i>	Western diamondback rattlesnake	Southwestern
<i>C. cerastes^a</i>	Sidewinder	Southwestern
<i>C. cerberus</i>	Arizona Black rattlesnake	Arizona
<i>C. helleri</i>	Southern Pacific rattlesnake	Southern California
<i>C. horridus</i>	Timber rattlesnake	Southern, Eastern
<i>C. lepidus klauberi</i>	Banded rock rattlesnake	Southwestern
<i>C. lepidus lepidus</i>	Mottled rock rattlesnake	Southern
<i>C. mitchelli pyrrhus</i>	Speckled rattlesnake	Southwestern
<i>C. molossus molossus</i>	Black-tailed rattlesnake	Southwestern
<i>C. oreganus</i>	Western rattlesnake	
<i>C. o. abyssus</i>	Grand Canyon rattlesnake	Northern Arizona
<i>C. o. concolor</i>	Midget Faded rattlesnake	Western
<i>C. o. lutosus</i>	Great Basin rattlesnake	Western
<i>C. o. oreganus</i>	Northern Pacific rattlesnake	Northwestern
<i>C. ornatus</i>	Chihuahuan Black Tailed rattlesnake	Texas
<i>C. pricei</i>	Twin-spotted rattlesnake	Arizona
<i>C. ruber</i>	Red diamond rattlesnake	Southern California
<i>C. scutulatus scutulatus</i>	Mojave rattlesnake	Southwestern
<i>C. stephensi</i>	Panamint rattlesnake	Western
<i>C. tigris</i>	Tiger rattlesnake	Arizona
<i>C. viridis nuntius</i>	Hopi rattlesnake	Western
<i>C. viridis viridis</i>	Prairie rattlesnake	Western
<i>C. willardii^a</i>	Ridgenose rattlesnake	Southwestern
<i>Sistrurus</i>	Pigmy rattlesnakes and massasauga	
<i>S. catenatus catenatus</i>	Eastern massasauga	Great Lakes region
<i>S. catenatus edwardsi</i>	Desert massasauga	Southwestern
<i>S. catenatus tergeminus</i>	Western massasauga	Central, Southern
<i>S. milarius^a</i>	Pigmy rattlesnake	Southeastern
<i>Agkistrodon</i>	Copperheads and cottonmouths	
<i>A. contortix^a</i>	Copperheads	Southern, Eastern
<i>A. piscivorus^a</i>	Cottonmouths	Southern, Southeastern

^aSubspecies not listed

when present, a rattle is not always heard before a strike. Cottonmouths and Copperheads do not possess a rattle (Fig. 1).

Crotalids are found in nearly all US states. Although not endemic to Alaska, Hawaii, and Maine, venomous snakebites have been reported in all states except Hawaii [1]. Snake bites are most common in the south, with Florida and Texas reporting the greatest number of bites nationally, and Arizona reporting the greatest number of bites per capita [1]. The average number of native venomous snakebites reported to US

poison centers each year is approximately 5000; however, not all bites are reported and the true incidence is likely higher [1]. Most bites occur in the warm months, between April and September [1, 2].

Crotalinae species do not “attack” humans and will avoid encounters if possible. As a result, many snakebites occur following intentional interaction with the snake by the patient. At-risk populations include herpetologists, religious snake handlers, and those who work outdoors in snake-endemic areas [3]. Others at risk are those who decapitate

Fig. 1 The characteristic rattle, elliptical pupil, and heat-sensing pit (posterior to nostril) can be seen on this speckled rattlesnake (*C mitchelli*)

a rattlesnake and subsequently pick up the head. Persistent reflexes in the venom apparatus allow the snake's head to "bite" the handler and deliver venom [4]. Perhaps due to increased propensity toward risk-taking behavior, bites are much more common in men than in women, with males typically comprising 70–80% of subjects in reported case series. Children are also frequent bite victims, however, representing 10–20% of subjects in various studies [1, 2]. Bites most often involve the upper or lower extremity, though bites to the head, neck, and torso are also reported. Many series report a preponderance of upper extremity bites, consistent with intentional interaction with the snake [2].

In the USA, rattlesnakes are responsible for the greatest morbidity and mortality due to crotaline envenomation. While an uncommon cause of death, a handful of fatalities are reported annually [1]. Despite the low mortality rate, rattlesnake envenomation can produce serious morbidity. Permanent tissue loss, especially following envenomations to a digit, is not uncommon. Good data on outcomes following North American snake envenomation are not available, but in a small prospective study of patients with copperhead envenomation, functional disability lasted 1–3 weeks in most patients [5]. Patients with more severe rattlesnake envenomations may have a longer recovery time.

Biochemistry and Clinical Pharmacology

Snake venom is a complex mixture of enzymatic and nonenzymatic proteins, polypeptides, lipids, biogenic amines, metal ions, and amino acids. Crotalinae venom contains a large variety of toxins, many of which produce physiologic effects in humans, and only some of which are characterized and fully understood. While some toxins are expected to be present to a certain extent in all North American crotaline venoms, the specific composition of venom in an individual snake may vary with the age, diet, and geographic location of the snake. Even snakes of the same species and general geographic location may differ in the toxicity of their venom [6].

Medically important components in crotaline venom include snake venom metalloproteinases (SVMPs), snake venom serine proteases (SVSPs), and phospholipases A₂ (PLA₂s). Other significant toxins include disintegrins, bradykinin potentiating peptides (BPPs), and C-type lectin-like proteins. Other toxins found in snake venoms may be less relevant to crotalid envenomation, such as vascular endothelial growth factors, which induce hypotension and increase vascular permeability, and cysteine-rich secretory proteins, which may block ion channels [7]. Snake venom toxins may act independently or synergistically on different cellular targets and organ systems to produce the observed clinical effects.

Snake venom metalloproteinases are enzymes with catalytic activity which is dependent on metal (usually zinc) ions. Dozens of SVMPs have been characterized in snake venom. They may produce many effects, including inflammation, proteolysis, and hemorrhage, contributing to local tissue toxicity; pro-coagulant or anticoagulant effects, contributing to coagulopathy; and antiplatelet actions. Hemorrhagic SVMPs act to damage the vascular endothelium and increase vascular permeability [8]. This may lead to extravasation of plasma and blood at the site of local injury manifesting as tissue edema and ecchymosis. In combination with coagulopathy and/or thrombocytopenia, hemorrhagic SVMPs may increase risk of bleeding [9–11]. Many

Fig. 2 Comparison of a normal clotting pathway (A) and fibrinogenolysis and fibrinolysis by crotaline venom (B and C). The normal pathway (A) requires thrombin to cleave fibrinopeptides a and b to form fibrin and to activate factor XIII to form XIIIa to catalyze covalent cross-linking and thereby produce an insoluble clot. Crotaline snake venom contains enzymes that degrade fibrinogen directly

to incoagulable fibrinogen and fibrinopeptides (C). Thrombin-like crotaline enzymes form “soluble” clots that are rapidly lysed by plasmin (B). Endogenous components of the coagulation system appear in ovals. **Boldface arrows** represent the pathway steps most affected by crotaline venom. *FDPs*, fibrin degradation products

SVMPs possess fibrinogenolytic and/or fibrinolytic activity. Fibrinogenolytic SVMPs preferentially cleave either the alpha or beta chain of fibrinogen. This results in degradation of fibrinogen without production of fibrin.

While most fibrino(geno)lytic enzymes in venom are metalloproteinases, some are serine proteases. SVMPs more often cleave the alpha chain of fibrinogen preferentially, while serine proteases tend to cleave the beta chain. Like the SVMPs, many serine proteases have both fibrinogenolytic and fibrinolytic activity, but some act only on fibrinogen [10]. Other serine proteases deplete fibrinogen through a thrombin-like effect. These thrombin-like enzymes (TLEs) release either fibrinopeptide A or B from

fibrinogen, rather than both fibrinopeptide A and B. Unlike thrombin, TLEs do not activate Factor XIII, and as a result, cross-linking of fibrin does not occur and a stable fibrin clot does not form. Rather, a friable, translucent, and easily degraded fibrin clot results, with an overall anticoagulant effect produced clinically [10, 12, 13] (Fig. 2). Some TLEs, such as crotalase, present in *Crotalus adamanteus* venom, also possess kinin releasing activity [14]. Some SVSPs have a direct anticoagulant effect through activation of Protein C. Snake venom metalloproteinases may also possess hemorrhagic activity, whereby they disrupt the basement membrane leading to loss of capillary integrity and local hemorrhage at the wound site [10, 11]. Other actions of SVSPs include

effects on platelets, such as inhibition or promotion of platelet activity, or reduction of platelet availability.

Hundreds of PLA₂ enzymes have been identified in snake venoms. They have diverse actions and may contribute to many effects of envenomation, including local tissue toxicity, neurotoxicity, myotoxicity, and hemotoxicity [13, 15]. Neurotoxic PLA₂s are found in the venom of some North American Crotalinae species. *Crotalus scutulatus* (the Mojave rattlesnake) is most well known for possessing a specific neurotoxin, called Mojave toxin. This toxin is a heterodimer composed of an alpha subunit without PLA₂ activity and a beta subunit with PLA₂ activity. The neurotoxin acts presynaptically to prevent acetylcholine release [16, 17]. Related neurotoxins in other crotaline species include canebrake toxin, isolated from some populations of *C. horridus* (the Timber rattlesnake), and a neurotoxin identified in some populations of *C. helleri* (the Southern Pacific rattlesnake) [15, 17].

Disintegrins are small nonenzymatic proteins which affect platelets. Disintegrins bind to the GPIIb/IIIa receptor on platelets to prevent fibrinogen binding and inhibit platelet aggregation. They may also inhibit platelet aggregation by binding fibronectin receptors and other integrins on the surface of endothelial cells and fibroblasts [7]. Disintegrins in *C. scutulatus* and *C. adamanteus* venom have been shown to produce antiplatelet activity through multiple mechanisms [9, 18].

Bradykinin-potentiating peptides have been isolated from venom of various Crotalinae snakes. The first BPPs were identified in *Bothrops jararaca* venom, and this discovery led to the development of captopril, the first angiotensin-converting enzyme (ACE) inhibitor. BPPs may induce formation of bradykinin or may inhibit the breakdown of bradykinin by ACE. Increased bradykinin may produce vasodilatory and hypotensive effects [19, 20]. Bradykinin-potentiating peptides may also stimulate nitric oxide generation by endothelial cells and leukocytes and cause eicosanoid release, contributing to local inflammatory effects. A bradykinin inhibitory peptide has also been identified in Crotalinae venoms [20].

C-type lectin-like proteins are nonenzymatic proteins that may affect plasma components and

blood cells, leading to hemorrhage. They may possess pro-coagulant, anticoagulant, and platelet modulating activities. CLPs found in venom of some Crotalinae species have been shown to inhibit thrombin. Other crotaline CLPs affect platelets through interactions with various platelet receptors and von Willebrand factor (VWF). Botrocetin, for example, a CLP found in *Bothrops* venom, forms complexes with VWF and the platelet receptor GPIb resulting in platelet activation [21, 22].

The venom of individual rattlesnakes, even within the same species, may possess a predominance of certain toxins. Venom is sometimes classified by SVMP activity versus lethal toxicity in mice, for which there appears to be an inverse relationship. Venoms with high SVMP activity and lower toxicity have been described as type 1 venoms, whereas venoms with low SVMP activity but high lethal toxicity have been described as type 2 venoms. While lacking in SVMP activity, type 2 venoms tend to be rich in other specific toxins, such as PLA₂ neurotoxin [23]. Such variation in venom within species has been described for *C. oreganus*, *C. horridus*, and *C. scutulatus* [16, 23, 24].

Pathophysiology of Toxic Effects

When a snake bites, venom is usually deposited in the subcutaneous tissues. Only rarely do fangs penetrate fascia, depositing venom intramuscularly. Absorption of venom by the lymphatic system begins immediately [25]. A depot of venom may remain at the bite site for several hours, leading to ongoing absorption of venom [26]. Venom antigens have been shown to be present in the circulation for 2 weeks following envenomation [27, 28].

Local Tissue Effects

Local tissue inflammation and edema are characteristic of crotaline envenomation. The most important contributors to this inflammatory process appear to be PLA₂s and SVMPs. Snake venom

serine proteinases may also contribute to inflammation and have been shown to activate endogenous matrix metalloproteinases [29]. Experimental models have shown that injection of crotaline venom leads to an increase in serum nitric oxide levels and release of pro-inflammatory cytokines and eicosanoids, with recruitment of leukocytes to the bite site, and ultimately development of a profound inflammatory response [29, 30]. Snake venom metalloproteinases, PLA₂s, SVSPs, and endogenous inflammatory mediators may all act together to produce capillary basement membrane damage, resulting in extravasation of plasma from the microcirculation, edema, and ecchymosis. Microvascular damage produced by hemorrhagic SVMPs may dispose to significant subcutaneous bleeding even in the absence of thrombocytopenia and coagulopathy. Snake venom metalloproteinases have also been associated with blister formation [15, 29, 30].

Hematologic Effects

Coagulopathy following crotaline envenomation is primarily due to the action of TLEs on fibrinogen. Both TLEs and fibrino(geno)lytic enzymes produce an overall anticoagulant effect resulting from degradation of fibrinogen with failure to produce a stable fibrin clot. Hemotoxins in North American crotaline venom do not activate the clotting cascade or affect clotting factors. The pathophysiological mechanisms for thrombocytopenia in the setting of crotaline envenomation are less well understood than for coagulopathy, and there are likely multiple contributing toxins and mechanisms. Venom may contain both disintegrins and CLPs, which may act in different ways to aggregate or inhibit platelets. Hemorrhagins in venom may also damage the blood vessel endothelial wall, leading to extravasation of blood and fluids.

Although bleeding is uncommon following envenomation by North American Crotalinae, the combined actions of coagulants, anticoagulants, platelet modulators, and hemorrhagins in venom present risk for severe bleeding, especially in the setting of injury.

Neurotoxic Effects

Snake venom neurotoxins are categorized as alpha and beta neurotoxins. Alpha-neurotoxins antagonize the postsynaptic nicotinic acetylcholine receptor and are found in venom of many Elapidae snakes [31]. Beta neurotoxins have been found in venom of many snake families, including Crotalinae. Beta neurotoxins in rattlesnake venom, such as Mojave toxin found in some populations of *C. scutulatus*, act presynaptically to inhibit neuronal release of acetylcholine [32]. This may lead to severe weakness, and in some cases paralysis, which may last many weeks.

The pathophysiologic mechanism behind venom-induced myokymia or fasciculations is less clear. The terms myokymia and fasciculations are often used interchangeably in the snakebite literature and are difficult to distinguish clinically. Myokymia represents bursts of multiple motor unit action potentials, which on electromyography are recorded as doublets, triplets, or multiplets. Myokymia has been documented following *C. horridus* (Timber rattlesnake) envenomation [33]. Fasciculations are single motor unit potentials. Although often described as fasciculations, the undulating involuntary contractions of muscles noted following envenomation by several Western US species, including *C. scutulatus*, *C. atrox*, *C. helleri*, and *C. cerastes*, may represent myokymia [34–36]. It is theorized that venom-induced myokymia may occur as a result of interaction of venom components with calcium or calcium-binding sites at the peripheral nerve membrane. However, effect on potassium channels, as occurs with other acquired myokymic syndromes, has also been suggested [32, 33].

Cardiovascular Effects

Crotalid snake venom toxins do not appear to have direct cardiac toxicity; however, rare cases of stroke and myocardial infarction associated with envenomation have been reported [37–39].

Venom-induced hypotension and/or shock may develop as a result of different mechanisms. Unabated fluid extravasation from damaged

microvasculature over hours to days can lead to significant hypovolemia and subsequent hypotension. Patients with previous exposure to snake venom may develop IgE antibodies to venom antigens, resulting in anaphylactic reaction following subsequent envenomation. Hypotension, at times accompanied by angioedema, may also occur in response to increased bradykinin resulting from the effect of BPPs in venom.

**Clinical Presentation
and Life-Threatening Complications**

It is estimated that approximately 80% of crotaline snakebites result in delivery of venom [40]. Thus, the remaining 20% of bites are “dry,” without venom deposition. Patients with dry bites will not experience any symptoms following a snakebite and will exhibit only puncture marks, scratches, or lacerations on physical examination.

For those patients with envenomation, the clinical presentation can be highly variable and exist along a wide spectrum. Specific clinical effects that develop, as well as the severity of the effects, may depend upon the composition of the venom to which the patient is exposed, the amount of venom delivered and absorbed, and other patient-related factors, such as co-morbidities and medication use. The location of the bite (i.e., head and neck vs. distal extremity) may also influence the presentation. An envenomation can range from very mild, with only minimal localized swelling on presentation that improves over hours without intervention, to life-threatening, with rapid development of airway compromise and cardiovascular collapse occurring within minutes of the bite. Most typically, patients exhibit findings somewhere between the ends of this spectrum. Additionally, findings at presentation to health care rarely represent peak severity of effects. In rare cases, swelling may not be immediately apparent and may take up to 8–12 h to develop, yet can become significant. Envenomation is a dynamic process, which may continue to evolve for days following the bite if not treated (and sometimes despite treatment).

Table 2 Clinical effects of crotaline envenomation

<i>Common</i>
Local Tissue Damage:
Edema
Ecchymosis
Erythema
Hemorrhagic bullae
Dermonecrosis
Hemotoxicity:
Coagulopathy
Thrombocytopenia
Neurotoxicity:
Myokymia
<i>Less Frequent</i>
Compartment Syndrome
Paralysis
Myonecrosis
Rhabdomyolysis
Shock
Angioedema
Bleeding
Vomiting and Diarrhea

Of the US crotalids, rattlesnake envenomations are associated with the most severe clinical presentations, followed by cottonmouth, and then copperhead envenomations. However, even copperhead envenomations may be serious, and although not reported in the peer-reviewed medical literature, a death has been attributed to anaphylaxis following a copperhead bite in the lay press [41].

The most common effects of native pit viper envenomation are swelling and pain, which occur in the majority of envenomations. Hematologic findings are common in rattlesnake envenomations but less so in cottonmouth and copperhead envenomations [2, 42]. Neurotoxicity and cardiovascular toxicity are less common, but may be life-threatening when they occur. Nonspecific systemic effects include metallic taste, anxiety, tachycardia, and nausea. Vomiting and diarrhea may also occur. Repeated episodes of vomiting or diarrhea may signal impending severe systemic toxicity, with hypotension or angioedema. (Table 2)

Local Tissue Effects

One or more puncture wounds, small lacerations, or scratches are nearly always present in the setting of pit viper envenomation, although there is one documented report of rattlesnake envenomation where only a small area of ecchymosis was noted at the bite site [34]. Most often, one or two puncture wounds are seen. Early after envenomation, pain and swelling develop locally at the bite site, and there may be oozing of blood or sero-sanguinous fluid from wounds. Ecchymosis and erythema are common findings but are not universally present. Ecchymosis is often a prominent finding in foot bites, where the entire dorsal aspect of the foot may exhibit a bluish tinge (Fig. 3). Toes remain pink and well perfused however, with preserved sensation and motor function, which helps to distinguish the blue appearance of the foot from cyanosis.

As venom is absorbed, swelling and pain increase. With distal extremity bites, patients may develop pain and tenderness along lymphatic pathways even prior to proximal extension of swelling. Axillary nodes are commonly tender following upper extremity envenomations and inguinal nodes are tender after lower extremity envenomations. Erythema, lymphangitic streaks, and ecchymosis may also extend along these pathways, dissociated from swelling (Fig. 4).

Fig. 3 Following a rattlesnake bite to the ankle, subcutaneous bleeding produced a bluish discoloration to the dorsal aspect of the foot

It is impossible to predict the ultimate extent of swelling in the first hours after an envenomation. If left untreated, one distal extremity envenomation might progress to involve only the lower leg or forearm prior to cessation of swelling, while another might continue to swell for days, until the entire extremity and the trunk are involved. Unabated extravasation of fluid and blood from “leaky” capillaries can lead to anemia, hypovolemia, and hypotension. Most bites are to a distal extremity, but occasionally patients are bitten in the head or neck. In these cases, progressive edema and swelling present a high risk of airway obstruction.

Superficial necrosis of the dermis, with development of hemorrhagic bullae, is a common finding after direct envenomation of a digit. In the first hours after a bite, faint cyanosis may be noted at the bite site. This may evolve into hemorrhagic bullae over the first 12–36 h after envenomation. If dermonecrosis does not develop within 1–2 days of the bite, it is not likely to occur. However, if blisters develop, they may continue to expand over several days. Deeper tissue necrosis may progress over a week or more. Extensive or circumferential hemorrhagic bullae involving large portions of the digit are more likely to be associated with necrosis of deeper tissue structures than are small bullae. Superficial dermonecrosis most often occurs on digits, but may rarely occur in other sites (Fig. 5).

Fig. 4 Following a rattlesnake bite to the foot, this patient exhibited proximal bruising along lymphatics

Fig. 5 Hemorrhagic bullae involving large areas of the digit are more likely to be associated with necrosis of deeper tissue structures

Compartment Syndrome

Swelling due to snake envenomation is often very severe, causing extreme expansion and deformity of the digits, hand, foot, arm, or leg. The swelling can feel tense on examination and the patient may have exquisite tenderness and great pain. Pulses may be difficult to palpate due to swelling. Clinically, it can be impossible to determine whether a patient has a compartment syndrome. Since venom is most often deposited subcutaneously, superficial to the muscle fascia, compartment syndrome is rare. However, it may occur and anecdotally seems to be more common in patients bitten in the anterior compartment of the leg. Since clinical examination is so unreliable in diagnosing compartment syndrome in snake envenomation, objective measurements of compartment pressures must always be performed and documented to be elevated prior to performing a fasciotomy. In the author's practice, clinical findings that may prompt measurement of compartment pressures include very tense tissue overlying a muscle compartment, decreased motor or sensory function distally that is inconsistent with the degree of soft tissue swelling, or severe pain out of proportion to physical examination findings that is not easily treated with analgesics.

Digits do not have true compartments, but due to the limited ability of the skin to expand to accommodate swelling, increased pressure may develop

risking neurovascular structures. Patients may present with pale, cool, or even blue and insensate digits, necessitating emergent neurovascular decompression, or digit dermatomy [43, 44].

Hematologic Effects

After local tissue effects, coagulopathy and thrombocytopenia are the most common findings associated with rattlesnake envenomation. In the Southwest USA, nearly two thirds of patients with rattlesnake envenomation develop coagulopathy and approximately one third develop thrombocytopenia [2]. Thrombocytopenia is a common feature of Timber rattlesnake (*C. horridus*) envenomation [45]. Coagulopathy and thrombocytopenia are uncommon following native *Agkistrodon* envenomations, although they may occur [42].

Coagulopathy results primarily from degradation of fibrinogen, which may occur within minutes of envenomation or may develop and progress more slowly over many hours. Native crotaline venom does not deplete other clotting factors. The isolated fibrinogen deficiency results in elevation of the prothrombin time (PT). Fibrin degradation products may also be elevated. Bleeding usually does not occur, although risk is increased when there is no measureable fibrinogen. Disseminated intravascular coagulation (DIC) is not a feature of venom-induced coagulopathy [46, 47].

Thrombocytopenia may also develop rapidly and be severe, or, alternatively, platelet count may begin to drop hours after a bite and continue to slowly decrease for days. As with coagulopathy, venom-induced thrombocytopenia is not typically associated with bleeding. However, when platelet counts are very low, patients are more likely to exhibit minor bleeding, such as oozing of blood from puncture sites and gums. Bleeding risk also appears to be increased when severe venom-induced coagulopathy and thrombocytopenia coexist or when patients are chronically using antiplatelet or anticoagulant medications at the time of envenomation [48].

Although serious systemic bleeding is very rare, subcutaneous bleeding near the envenomation site may occur in the days following the bite due to combined effects of venom hemorrhagins and other toxins that produce microvascular injury, especially when coagulopathy or thrombocytopenia are present. This can lead to a significant drop in hemoglobin, with continued swelling, pain, ecchymosis, and tenderness in the extremity.

Late Hematologic Toxicity

After the acute envenomation and treatment phase, during which venom-induced hemotoxicity is either identified and treated or prevented with administration of antivenom, the patient enters a subacute phase of the envenomation which may last several weeks. During this time the patient may continue to have absorption and circulation of venom antigens, placing the patient at risk for late hemotoxicity as any antivenom they received is eliminated from the body. Late (either delayed onset or recurrent) hematologic toxicity is thought to result from differences in pharmacokinetic properties between venom and antivenom. As it is of smaller molecular size, Fab antivenom undergoes more rapid clearance than venom. It is also theorized that venom and antivenom complexes may dissociate, and that there may be delayed absorption of venom from tissue depots [49–51].

It is not clear exactly why late hematologic toxicity develops in some patients and not in others. Predictors for recurrence or delayed onset of hematologic toxicity have not been identified, and all patients treated with Fab antivenom following rattlesnake envenomation are considered at risk. While patients with severe coagulopathy or thrombocytopenia during the initial treatment phase appear to be at increased risk for developing recurrence, even patients with completely normal fibrinogen levels and platelet counts during their acute treatment phase may develop hematologic toxicity days after treatment [52, 53]. Although bleeding complications are uncommon with late hematologic toxicity, life-threatening and fatal bleeding events have been reported [48, 54–56]. One retrospective study compared bleeding

events in patients on anticoagulant or antiplatelet medications to patients not taking these medications. An increased risk of both early and late bleeding was found in patients using anticoagulants or antiplatelet agents (relative risk = 6.8; 95% CI = 2.82–16.4) [48].

Neuromuscular Effects

The most common neurological finding associated with North American crotalid envenomation is myokymia (often described as fasciculations). Myokymia appears as wavy, rolling, involuntary contractions of muscles, sometimes referred to as a bag of worms under the skin. Timber rattlesnakes (*C. horridus*) are best known for producing myokymia, although the finding of myokymia or fasciculations has now also been reported in several Western *Crotalus* species [33–36, 45]. Myokymia or fasciculations may be associated with muscle weakness leading to respiratory failure. Case reports and a retrospective poison center study suggest that patients with fasciculations in the shoulder, chest, or diaphragmatic areas are at risk for progression to respiratory failure, possibly due to incoordination of respiratory muscles [36, 46].

The Mojave rattlesnake (*C. scutulatus*) is famous for its neurotoxic venom and potential to produce paralysis. However, there are few reports in the literature of respiratory failure or paralysis due to Mojave envenomation, which may be attributable to the presence of Mojave toxin in only some populations of *C. scutulatus*. In these reports of paralysis, myokymia or fasciculations are not described. In one such report, a young child developed progressive weakness and respiratory failure 30 h after envenomation despite treatment with Antivenin Crotalidae Polyvalent (ACP) antivenom [47]. Similar neurotoxic effects have been reported following Timber rattlesnake (*C. horridus*) envenomation, for which some populations possess crototoxin, a neurotoxin analogous to Mojave toxin. In one report, a child developed weakness and paralysis, without documentation of myokymia, after a Timber rattlesnake bite. In this case, the weakness did not respond to Fab antivenom, required prolonged

mechanical ventilation, and was associated with severe rhabdomyolysis [48].

Rhabdomyolysis is another feature of envenomation by some crotaline snakes. A subpopulation of the Timber rattlesnake (*C. horridus*), formerly classified as a subspecies known as the Canebrake rattlesnake (*C. h. atricaudatus*), is particularly known for producing systemic rhabdomyolysis. Patients envenomated by the Timber rattlesnake in southern Georgia and northern Florida have been reported to have creatinine phosphokinases (CPKs) measured over one million IU/L, without localized myonecrosis [49]. In general, significant rhabdomyolysis following snake envenomation is often associated with neurotoxic findings. Most North American snake envenomations do not produce rhabdomyolysis.

Systemic Effects

Some patients develop severe systemic toxicity, with hypotension and shock, following rattlesnake envenomation. Hypotension may occur for different reasons. Patients who have previously been sensitized to snake venom proteins may develop IgE antibodies to venom and experience acute anaphylaxis when bitten. In such cases, the anaphylactic reaction occurs in parallel to envenomation, and when severe can be difficult to distinguish from systemic effects due to venom toxicity. Clinical findings of venom-induced anaphylaxis are the same as those occurring with anaphylaxis due to any cause, and may include urticaria, rash, bronchospasm, hypotension, and when severe, shock and acidosis [62].

Hypotension may also result from the action of bradykinin potentiating peptides in venom, possibly with contribution from other vasoactive venom components [19, 63]. Patients typically develop symptoms within the first hour after envenomation. Some patients will have a depressed level of consciousness, hypotension, and shock within minutes of the bite. Others may develop vomiting and diarrhea prior to onset of hypotension. Angioedema resulting in airway obstruction may also occur.

Rattlesnake envenomation causes fluid to extravasate from microvasculature near the bite site and can lead to extensive third-spacing with significant intravascular hypovolemia and anemia if left untreated. In such cases, patients may have delayed onset of hypotension. Since most rattlesnake envenomations produce some degree of hypovolemia, often evidenced by hemocentration on initial laboratory analyses, dehydration or ethanol intoxication at the time of envenomation may also predispose to development of hypotension.

Hypotension and shock may also result from bleeding. On occasion, patients develop serious bleeding after envenomation, usually in the setting of both severe thrombocytopenia and afibrinogenemia. Venom-induced thrombocytopenia and coagulopathy do not represent disseminated intravascular coagulation (DIC). However, in rare cases, activation of the clotting cascade with DIC has been reported following rattlesnake bite, such as with a case of direct vascular envenomation [64].

Diagnosis

The diagnosis of snake envenomation is usually straightforward, based on history of a snakebite and presence of physical findings consistent with envenomation. Unfortunately not all patients see the snake, and the diagnosis should always be considered in areas where pit vipers are endemic and a patient presents with a bite, sting, or puncture wound of unknown origin. Children in particular are at risk when playing outdoors and may be unable to report what happened. Children with a puncture wound and unexplained progressive swelling should be monitored closely for a possible pit viper envenomation.

The diagnosis of snake envenomation is dependent on physical examination findings and sometimes laboratory studies. One or more punctures, small cuts or other disruption to the dermis should be present, with swelling and pain developing at the site. If swelling is not present, laboratory studies may aid in diagnosis. While most rattlesnake envenomations produce swelling, occasionally patients may exhibit significant

thrombocytopenia or coagulopathy without appreciable swelling.

All patients with potential pit viper envenomation should have a platelet count, fibrinogen level, and PT obtained. Prothrombin times rise as a result of fibrinogen consumption and return to normal faster than fibrinogen levels, as clotting function is restored [50]. Some clinicians also assess fibrin degradation products (FDPs). Since baseline fibrinogen levels range widely and fibrinogen is an acute phase protein which may rise in response to inflammatory effects of venom, elevated FDPs in the setting of “normal” fibrinogen may reveal fibrinolytic activity that would otherwise be undetected. Other laboratory studies which may aid in management include a baseline hemoglobin and hematocrit, and in patients who present with evidence of shock, electrolytes, liver and renal function tests, and arterial blood gases. Patients with neurologic findings or concern for compartment syndrome should also have a CPK measured.

If there are no clinical signs of envenomation and laboratory studies (platelet count, fibrinogen, prothrombin time) are completely normal, the patient may have a dry bite. However, evidence of envenomation can be delayed in onset for more than 8 h. Therefore, patients with potential dry bites should be observed for 8–12 h prior to discharge with diagnosis of a dry bite. During this time, serial physical examinations as well as reassessment of platelets and fibrinogen at least 4 h from the time of the initial laboratory assessment and eight hours from the time of the bite should be performed [40].

Treatment

Snakebite management begins with immediate airway support when necessary, intravenous fluid resuscitation, and close monitoring for hypotension or other evidence of systemic toxicity. While the specific supportive therapies indicated vary depending on the presentation and progression of the envenomation, the definitive treatment for a serious or progressing North American rattlesnake envenomation is antivenom (LOE III).

After a snakebite, patients should be placed on a cardiac monitor and have intravenous access established in an unaffected extremity. An initial 20 mL/kg fluid bolus is appropriate even in the absence of symptoms, since envenomation will lead to third spacing of fluids and many patients present with early laboratory evidence of hemoconcentration. Initial laboratory studies to be obtained include a complete blood count, fibrinogen level, and prothrombin time. If unable to measure fibrinogen, then a D-dimer, fibrin monomer, or fibrin degradation products can be helpful. Ill-appearing or unstable patients, as well as those with evidence of neurotoxicity, should also have renal function studies, electrolytes, and a CPK measured. An electrocardiogram and chest radiograph should be obtained in patients with chest pain or respiratory distress.

All constrictive clothing, bandages and rings should be removed. Pressure immobilization bandages (PIBs) are sometimes placed in the field, although not recommended for the treatment of North American Crotalinae envenomation [51]. Although PIBs have been shown to delay systemic absorption of snake venom and are used in the prehospital management of elapid envenomations in Australia, the bandages have been shown to increase tissue necrosis and compartment pressures in an animal model of crotaline envenomation when compared to controls [52]. There are rare case reports of clinical deterioration following removal of constrictive bandages [53], however, the risk of such an event appears to be very low. In most cases, pressure bandages are applied incorrectly and are either too loose or too tight [54, 55]. Decreased perfusion to the extremity resulting from tight bandages and tourniquets may produce greater risk to the extremity than the bite itself. It is thus recommended that pressure bandages and tourniquets be removed, without waiting for antivenom availability. (Level of evidence (LOE III))

The affected extremity should be extended and immobilized with a posterior splint, and the splint loosely secured to the extremity with a nonconstrictive dressing. Immobilization may improve comfort and prevents the patient from

holding the extremity in a flexed position at the elbow or knee, which can trap edema, increase pain, and delay functional recovery. Children in particular tend to keep the knee bent at 90° and later have difficulty extending the knee and walking during the sub-acute phase of envenomation. After splinting, the immobilized extremity is then elevated above the level of the heart. For upper extremities, placing a stocking net around the splinted extremity and attaching the distal end to a raised IV pole provide maximal elevation. Lower extremities can be elevated on several pillows. Although evidence does not exist to support an association between a particular limb position and outcome, expert opinion is that elevation limits dependent edema and related pain in the distal extremity [40] (LOE III).

Some patients will present shortly after the bite with no symptoms or with only minimal swelling at the bite site. In such cases, the patient should be observed closely for development of symptoms, coagulation abnormalities, or progression of swelling, to determine if treatment with antivenom is indicated. There are several ways to assess swelling. One common way is to draw a line on the skin at the “leading edge” of the swelling, repeating the measurement and drawing a new line every 15–30 min. Since not all patients have an obvious “leading edge” noted on physical exam, another common method is to draw an outline of a tape measure in three locations, such as the hand, forearm and arm, or the foot, leg, and thigh, and measure the circumference at these same locations every 15–30 min until stable, after which measurements can be done progressively less frequently. Asking the patient if pain and swelling are worsening and performing repeated physical assessments for tenderness along lymphatic pathways are also helpful in determining whether the envenomation is progressing. If it is determined that antivenom is indicated, the frequency of swelling assessments can be decreased to every 1–2 h until the envenomation is under control.

Most patients with a pit viper bite will develop swelling or other symptoms within 8 h of the bite, although sometimes onset of appreciable swelling

may take up to 12 h. Similarly, onset of thrombocytopenia and hypofibrinogenemia are expected to occur within that time frame. The author’s practice is to obtain laboratory studies to assess for hemotoxicity upon presentation and again 6–8 h after the bite. If a patient has not developed any signs or symptoms of envenomation in the first 8–12 h after the bite, the patient likely has a dry bite, without venom deposition, and can be safely discharged from the hospital [40] (LOE II-3).

More often than not, patients present with clear signs of envenomation after a pit viper bite. Usually this amounts to pain and obvious swelling at the bite site, but occasionally patients present with shock or pending airway obstruction. Patients with bites to the head or neck area, and those with angioedema, are at risk for airway obstruction and should be intubated early if evidence of airway compromise is noted. Others who may be at risk for respiratory failure are those with neurotoxicity (weakness or fasciculations/myokymia) or decreased level of consciousness due to shock. Myokymia has been reported to respond to calcium chloride infusion [33, 45]. Hypotension can be initially treated with normal saline or lactated Ringers boluses, but if blood pressure does not quickly respond to fluids, then epinephrine should be administered. Epinephrine acts directly on peripheral alpha-1 receptors to produce vasoconstriction, which counteracts the vasodilatory effects of venom. Patients can be placed on an epinephrine infusion, titrating as needed. Anaphylactic reactions to venom are treated the same as anaphylaxis due to other causes, with epinephrine, antihistamines, and steroids.

There is general agreement that antivenom is indicated for patients who exhibit progressive swelling, hematologic toxicity, neurotoxicity, or systemic toxicity. Blood products are not indicated in the routine management of venom-induced thrombocytopenia and coagulopathy. Patients with serious bleeding despite administration of antivenom may require transfusion of packed red blood cells to replace losses. Platelets and fresh frozen plasma may be indicated as part of a massive transfusion protocol when bleeding is severe. Some clinicians also administer

cryoprecipitate to replace fibrinogen when patients are bleeding in the setting of venom-induced coagulopathy. In the absence of bleeding, there is no evidence to support transfusion of platelets, even when platelet counts are very low. However, some clinicians will administer platelets when platelet counts fall below 10 K/mm^3 despite antivenom treatment. Unfortunately, thrombocytopenia that is resistant to antivenom treatment may not improve with platelet transfusions either, and platelet count may rise only transiently, if at all, due to continued venom effect. Crotaline venom does not directly affect coagulation factors; however, management of severe, life-threatening bleeding may result in a dilutional coagulopathy for which factor replacement may be necessary.

Local wound care includes cleansing and superficial debridement or decompression of tense bullae. Tetanus prophylaxis should be updated. Erythema is a common characteristic of rattlesnake envenomation, which appears to occur as a result of venom-induced inflammation. Retrospective reviews of North American crotaline envenomation reveal a very low incidence of infection. Prophylactic antibiotics are not recommended [56, 57] (LOE II-3). Rarely, some patients may develop late infection following envenomation and should be assessed for such if fever, new erythema, swelling, or tenderness localized to the bitten limb develop in the days to weeks following the snakebite.

Compartment Syndrome

Envenomation of an extremity often results in tense swelling and severe pain. Pulses may be difficult to palpate due to massive edema, and the patient may have difficulty moving the fingers or toes due to edema and pain. Severe swelling can also alter sensation. In such cases, it can be impossible to determine clinically whether or not a compartment syndrome is present. Compartment syndrome is uncommon following crotaline snake envenomation because the fangs typically

do not penetrate the fascia. Animal studies demonstrate that injection of Crotalinae venom superficial to the muscle does not lead to myonecrosis [58]. However, cases of compartment syndrome do occur and the clinician must consider the diagnosis. When suspected, direct measurement of compartment pressures should be performed. (LOE II-3)

An extensive review of the role of fasciotomy in the treatment of Crotalinae envenomation found little evidence to support the practice, even in the setting of elevated compartmental pressures [58]. When venom is injected subfascially, myonecrosis occurs due to the direct toxic effect of venom, and this myonecrosis is not prevented or improved with fasciotomy [58]. A porcine model of intramuscular envenomation demonstrated that fasciotomy does not decrease myonecrosis and may actually worsen it [59]. However, there are very few case reports and no studies demonstrating use of antivenom alone to treat elevated compartment pressure. One case report involved a 17-month-old girl with a copperhead bite who received 12 vials of Crotalidae Polyvalent Immune Fab antivenom. Subsequent measurement of intracompartmental pressure (ICP) in the anterior compartment of the leg revealed ICP of 85 mmHg (normal: 0–20 mmHg). The patient did not have evidence of neurovascular compromise. Another 6 vials of antivenom were administered and 2 h later both swelling and ICP were declining. An additional 8 vials were administered and the patient had recovery with full function of the leg without fasciotomy [60]. Other case reports of elevated ICP treated without fasciotomy document pressures less than 60 mmHg [61–63]. If compartment pressure is elevated and the patient has evidence of continued perfusion to the distal extremity, it is reasonable, based on current evidence, to give additional antivenom in an effort to lower compartment pressure and avoid fasciotomy. The patient requires close clinical monitoring however, and if the pressure is not declining in response to antivenom, or there is clinical deterioration, fasciotomy should be performed. (LOE III)

Digit Dermotomy

Fingers are a common site for envenomation and have limited ability to expand in size to accommodate inflammatory responses to venom. The digit itself can function as a small compartment, and on occasion patients will lose perfusion in the finger necessitating a dermatomy, or neurovascular decompression procedure. Most permanent tissue loss in the digits is related to direct venom toxicity and will not be prevented with prophylactic digital dermatomy. However, in patients who present with or develop a cold and pale or cyanotic digit, without evidence of perfusion, a dermatomy is recommended as soon as possible. This procedure involves a longitudinal incision through the skin along the radial or ulnar aspect of the digit to decompress the neurovascular bundles. The incision extends from the web space to the mid-portion of the distal phalanx, avoiding the neurovascular structures. Digit dermatomy is performed based on clinical diagnosis of “compartment syndrome” of the digit, since intracompartmental pressures cannot be measured [43, 44] (LOE III).

Antivenom

Antivenom is the definitive treatment for snake envenomation. Antivenoms are produced by immunizing animals against venom and then collecting the serum from the animals, purifying it, and precipitating desired antibodies. First-generation antivenoms, initially developed during the late 1800s, consist of minimally purified sera and are associated with high risk of acute and delayed hypersensitivity reactions. Second-generation antivenoms represent an improvement upon these crude antisera, in that they undergo purification techniques to remove unwanted protein components and concentrate whole immunoglobulins [64]. Whole IgG antivenoms are in common use throughout the world for the treatment of snake envenomation. Despite improved potency and purity compared to first generation antivenoms, high rates of acute and delayed

hypersensitivity reactions are reported with some whole IgG antivenoms. Antivenin Crotalidae Polyvalent, the only antivenom used to treat North American crotalid envenomation from the 1950s through the turn of the century, was a whole IgG product. Acute and delayed hypersensitivity reactions were frequent occurrences with use of this product [2, 65].

Antivenoms that are currently FDA-approved for use in the treatment of North American Crotalinae envenomation represent “third generation” antivenoms. The antibodies in these products are cleaved and purified to isolate the Fab or F(ab')₂ fragments. Antibody fragments generally have an improved safety profile over second-generation whole IgG antivenoms due to elimination of the immunogenic Fc portion of the antibody [64]. Despite this improvement in safety, caution must always be used when administering antivenom, since anaphylaxis or rate-related anaphylactoid reactions can occur with exposure to any animal-derived protein and may be life-threatening. All patients should receive antivenom in a monitored unit, such as an emergency department or intensive care unit.

The advent of whole IgG antivenoms purified using caprylic acid has the potential to change perceptions of safety for whole IgG antivenoms, as this technique appears to be associated with comparatively safe antivenoms, similar in overall safety profile to fractionated IgG antivenoms and with arguably similar or greater neutralizing potency, but significantly lower production costs [66].

Antivenoms work by binding and neutralizing venom antigens and enhancing their elimination. While antivenom can stop the progression of swelling and reverse some venom effects, such as coagulopathy, antivenom is not effective in reversing tissue injury that has already occurred. Antivenom has also not been demonstrated to prevent tissue necrosis. However, animal studies have demonstrated that antivenom can increase perfusion pressure and decrease compartment pressure in an extremity following intramuscular venom injection [67, 68].

The effectiveness of a particular antivenom at reversing a specific venom effect depends on the specificity of the antivenom for the venom antigens to which a patient was exposed. Polyvalent antivenoms offer protection against the venom of more than one snake species. Often, these antivenoms are also effective against snake venoms that are closely related to that of the species used to make the antivenom. However, efficacy against different venom effects may vary. Thus, an antivenom may not consistently reverse all effects of envenomation, even when indicated for treatment of envenomation by a particular species. For example, antivenom may or may not reverse neurotoxicity due to North American crotaline envenomation [35, 46]. Thrombocytopenia may also be refractory to treatment with antivenom [69]. In particular, thrombocytopenia following Timber rattlesnake (*C. horridus*) envenomation is known for resistance to antivenom [70].

Crotalidae Polyvalent Immune Fab (Ovine)

Crotalidae Polyvalent Immune Fab (Ovine) (CroFab[®]) is approved by the United States Food and Drug Administration (FDA) for use in the management of envenomation by all North American crotalid species. Although not FDA-approved for use in envenomations by nonnative crotaline snakes, CroFab has also been used with apparent success in a *Crotalus durissus* (South American rattlesnake) envenomation [71]. When administered with venom, CroFab has decreased lethality in mice from two South American crotaline venoms (*C. durissus* and *Bothrops atrox*) [72].

CroFab is made by immunizing sheep with venom from one of the following four North American snakes: *Crotalus atrox* (Western Diamondback rattlesnake), *C. adamanteus* (Eastern Diamondback rattlesnake), *C. scutulatus* (Mojave rattlesnake), and *Agkistrodon piscivorus* (cottonmouth). The ovine venom-specific immunoglobulins are collected and cleaved with papain to isolate the Fab fragments. Since small amounts of papain may be present in the final product, allergy to papain or papaya is considered a contraindication to CroFab [73]. After cleavage, the

four monovalent antivenoms are then mixed and prepared as a lyophilized powder in vials requiring reconstitution prior to use. The protein content of each vial is approximately 1 g [73]. The antivenom can be reconstituted in sterile water or normal saline. When done correctly, reconstitution of the lyophilized antivenom should take approximately 1 min [74]. A rapid and effective approach to preparation of antivenom is to take a 250 ml bag of saline, withdraw 20–25 mL and inject into a vial of CroFab until the vial is filled. As the vial fills, air must be withdrawn from the top of the vial. The bottles should be manually rolled and inverted to facilitate dissolution of the powder [74]. When solid particles have dissolved, the contents can then be drawn up and injected back into the original 250 mL bag. The reconstituted dose of antivenom (4–6 vials for a typical control dose), now dissolved in 250 mL of saline, can be administered over 1 h [73]. The infusion may be initiated at a slow rate, 25 mL per hour, for the first 5 min to ensure the patient does not develop an acute hypersensitivity reaction to the antivenom. After 5 min, the infusion rate should then be increased to the full 250 ml per hour [73]. Some authors have advocated administering CroFab as a continuous infusion, but this method has not been studied and is not recommended at this time [75].

CroFab should be initiated as soon as possible after diagnosis of envenomation is made and indications for antivenom are met. (LOE II-3) Early administration will ideally prevent further progression of local tissue effects which contribute to morbidity. For example, the more swelling that has occurred, the longer it will take for resolution and functional recovery. No time limit has been identified after which antivenom is no longer effective. There are cases reported in which antivenom was used successfully more than 24 h after envenomation [63, 76]. An evidence-informed treatment guideline is available to assist in clinical decision-making regarding administration of CroFab antivenom [40].

The initial dose of CroFab is 4–6 vials, unless the patient presents in shock or with serious active bleeding, in which case an initial dose of 8–12 vials has been recommended by

an evidence-based consensus [40]. This can be followed by additional 4–6 vial doses as needed to achieve initial control of the envenomation. The manufacturer describes “initial control” as complete arrest of local injury and return of coagulation abnormalities and systemic signs to normal [73]. This may be an overly optimistic target for establishment of initial control, and strict adherence to these guidelines may lead to unnecessary dosing of antivenom. While complete arrest of swelling and systemic toxicity (such as hypotension) should be criteria for initial control, resolution of hypofibrinogenemia may require several hours despite adequate antivenom administration. Additionally, local findings such as hemorrhagic bullae and ecchymosis may continue to progress for days and are not expected to arrest with antivenom treatment. Neurotoxic effects may respond to antivenom, but experience is mixed.

Once initial control is obtained, administration of maintenance doses is then recommended per the manufacturer’s prescribing information [73]. Maintenance antivenom consists of two vial doses which are given every 6 h \times 3 doses, for a total of six vials over 18 h. In clinical trials of this antivenom, maintenance doses were shown to decrease recurrence of local swelling in the first 24 h after control of the envenomation and to decrease the risk of late hematologic toxicity [73] (LOE I). All patients, particularly those with copperhead envenomations, which are generally less severe than rattlesnake envenomations, may not benefit from maintenance doses. Clinicians should speak with local medical toxicology specialists to determine the need for maintenance antivenom based on regional experience.

Acute hypersensitivity reactions to CroFab have been reported in 6% of patients. Although most reactions appear to be mild, are easily treated, and do not preclude completion of antivenom, severe life-threatening reactions with airway swelling and hypotension do occur [73, 77]. Delayed hypersensitivity reactions appear to be less common. These Type III hypersensitivity reactions, known as serum sickness,

develop between 3 days and 3 weeks after treatment and are characterized by urticaria, rash, arthralgias, fever, and myalgias [65]. They may be treated with antihistamines and corticosteroids.

Late Venom Toxicity Following Treatment with CroFab

After CroFab is administered, venom antigens are bound to antivenom and are no longer detected in the serum. As CroFab is eliminated, unbound venom antigens may return to the circulation. The elimination half-life of CroFab is estimated to be approximately 15 h [73]. The rate of clearance of unbound antivenom exceeds the rate of clearance of unbound venom antigens, which may be present in the circulation for weeks following an envenomation. This recurrent venomemia has been associated with recurrence of clinical venom effects [27, 28].

Local recurrence is the renewed progression of swelling after initial cessation following treatment with antivenom. In the initial clinical trial of CroFab, 27% of patients developed recurrent swelling in the first 24 h after antivenom treatment. In the second clinical trial, after initial control was established, patients were randomized to receive either scheduled maintenance doses of antivenom or “as needed” doses for recurrent venom effects. Local recurrence did not occur in patients who received maintenance doses [73, 78]. Patients who do not receive maintenance doses of antivenom should be observed in the hospital for 18 h following control of the envenomation with CroFab [40]. Local recurrence or worsening trends in platelets or fibrinogen during that time may be treated with additional antivenom. (LOE III)

Late hematologic toxicity is an important and potentially dangerous consequence of rattlesnake envenomation that has been treated with CroFab. In a clinical trial of CroFab where maintenance antivenom was not used, 53% of patients developed hematologic recurrence [78, 79]. With maintenance dosing following initial control, the incidence of late hemotoxicity was decreased [73]. In two subsequent cohorts of rattlesnake envenomation in Arizona, hematologic

recurrence was reported in 28.5% and 32% of patients receiving routine maintenance doses of antivenom [80, 81]. The risk of recurrence appears to be highest in patients who exhibit hematologic toxicity during their initial treatment phase. However, patients who had normal laboratory studies throughout their initial presentation and hospitalization have also been reported to develop late onset hematologic toxicity [80]. This is thought to be due to early prevention or “masking” of these effects by administration of antivenom. Predictors of late hematologic toxicity have not been identified. Data from one retrospective case series suggest that lack of fibrin degradation products or other evidence of coagulopathy, as well as normal platelets that do not rise >20% following CroFab treatment, may identify those patients who are not at risk for late toxicity [82]. However, larger studies must be done before recommendations can be made against diligent laboratory monitoring of all rattlesnake envenomation patients treated with CroFab. For patients with copperhead envenomations who do not exhibit hematologic toxicity during initial treatment, routine laboratory reassessment in the days to weeks following CroFab administration may not be necessary [42] (LOE III).

Delayed or recurrent coagulopathy and/or thrombocytopenia are relatively common following treatment of rattlesnake envenomation with CroFab, but are rarely associated with serious bleeding. Nonetheless, life-threatening and even fatal bleeding complications have occurred in this setting [83–86]. Clinicians must be diligent in monitoring patients for delayed or recurrent hematologic toxicity in the days to weeks following treatment. Patients should be warned to watch for evidence of hemotoxicity, such as excessive bruising, gingival bleeding, or hematochezia, and to avoid activities that place them at risk for injury, such as contact sports. Even minor surgeries should be avoided during the 2 weeks after CroFab treatment. It is strongly recommended that all patients have platelets, fibrinogen, and prothrombin time rechecked 2–3 days following

the last dose of antivenom and again 5–7 days following the last dose of antivenom. Some patients manifest late toxicity soon after treatment, but for others the initial laboratory evaluation may be normal yet they will still go on to develop severe hematologic toxicity, with undetectable fibrinogen and dangerously low platelet counts [81] (LOE III).

Not all patients with late hematologic toxicity require retreatment with antivenom. Mild to moderate coagulopathy, thrombocytopenia, or even a combination of the two can be managed with observation on an out-patient basis. When platelets or fibrinogen are first noted to drop, they should be repeated within a day or two depending on how severe the drop and how rapidly it developed. Retreatment with antivenom should be considered if platelets drop below 25 K/mm^3 regardless of fibrinogen level, if platelets drop below 50 K/mm^3 with fibrinogen less than 80 mg/dL , or if there is any evidence of bleeding or other risk of bleeding. Spontaneous bleeding is unlikely to occur above these cut-offs [78]. Isolated hypofibrinogenemia or afibrinogenemia does not require retreatment with antivenom if platelet count is normal. The risk of bleeding in the setting of isolated afibrinogenemia is low [78], and in the author’s practice such coagulopathy without thrombocytopenia is not routinely retreated with antivenom. However, if the patient has additional risk factors for bleeding or has been using aspirin or another antiplatelet agent that would render platelets dysfunctional, then the author’s practice is to retreat with antivenom. Other potential risk factors for bleeding that would favor retreatment for late hemotoxicity include high risk of injury (i.e., a toddler prone to falls), hypotension or shock following the initial snakebite event, pregnancy, or use of anticoagulant medications [83] (LOE III). The ideal treatment strategy for late hemotoxicity has not been identified. Initial antivenom doses ranging from 2–6 vials have been used with varying success in patients with delayed or recurrent hematoxicity. Late hemotoxicity can be refractory to retreatment with CroFab.

Crotalidae Equine Immune F(ab')₂

Crotalidae equine immune F(ab')₂ (Anavip[®]) received FDA approval for the treatment of North American rattlesnake envenomation in May 2015, although it is not expected to be available for commercial use in the USA until 2018. Anavip is made by immunizing horses with venoms from *Bothrops asper* and *Crotalus simus*. The immunoglobulins are isolated and cleaved with pepsin to yield F(ab')₂ fragments. These fragments have a longer elimination half-life than Fab fragments [27, 87]. The protein content is approximately 120 mg per vial. Anavip is provided in lyophilized form in vials that can be reconstituted with 10 ml of normal saline. Reconstitution can be achieved in less than 1 min with gentle swirling of the vials.

The initial dose of Anavip is 10 vials. After reconstitution of each vial, this total dose can be administered in a volume of 250 mL normal saline. The initial rate should be set at 25–50 mL per hour to observe for evidence of acute hypersensitivity. If the patient tolerates this rate for 5 min, the infusion rate should be increased to 250 mL per hour so that the entire dose is administered in 1 h. The patient should then be reassessed for signs of ongoing venom toxicity, such as continued progressive swelling, worsening thrombocytopenia or coagulopathy, or systemic effects such as hypotension. If control of the envenomation is not gained with the initial dose of Anavip, an additional 10 vial dose may be given. Reassessment and redosing should continue until the patient is stable and clinical signs of envenomation are not worsening. Once control of the envenomation has been established, the patient should continue to be observed for any reemergence of venom effects for 18 h after the last dose of antivenom. If swelling, hemotoxicity, or other symptoms do reemerge, then additional 4 vial doses of Anavip are indicated [87].

The advantage of Anavip over CroFab is a decreased risk of developing late coagulopathy or thrombocytopenia. (LOE 1) In a small phase 2 clinical trial where subjects were followed for 2 weeks, venom levels measured

via immunoassay remained undetectable throughout follow-up in those treated with Anavip, while venom levels rose during the follow-up period in four out of six subjects treated with CroFab. All subjects treated with CroFab developed late hemotoxicity in this study, while only one in the Anavip group developed late thrombocytopenia, with a platelet nadir of 127 K/mm³, and no Anavip subject developed hypofibrinogenemia [27]. In a subsequent phase 3 randomized, blinded, controlled trial, rates of late coagulopathy and thrombocytopenia were compared between three groups: Anavip with maintenance doses, Anavip without maintenance doses, and CroFab with maintenance doses. Late coagulopathy occurred in 10% of subjects receiving Anavip with maintenance and 5% of subjects receiving Anavip without maintenance. In the CroFab group, 30% of subjects developed late hematologic toxicity, consistent with previous studies. Interestingly, all (6) subjects in the Anavip groups who developed late hemotoxicity were enrolled at a single site in California, while the 11 subjects in the CroFab group with late hemotoxicity were distributed among seven sites in five states [88]. Future studies will need to determine if late hematologic toxicity following treatment with Anavip is truly limited to a single geographical area. There was no difference in incidence of immune reactions between groups [88]. Until Anavip becomes available for use and further clinical experience is gained, specific recommendations regarding use of Anavip vs. CroFab for the treatment of rattlesnake envenomation cannot be made.

Special Populations

Children

Children experience the same clinical manifestations as adults following snake envenomation [89]. Dosing of antivenom follows the same guidelines as that for adults, and total doses administered to children and adults are similar

[2, 73]. Fluid overload as a result of antivenom dosing has not been reported in children, but in very small children requiring large doses of antivenom, the drug may be diluted in lower total volumes of fluid if necessary and administered over 1 h.

Pregnancy

There is limited information available regarding outcomes in pregnant patients envenomated by North American rattlesnakes. Snake venom poses a risk to both the mother and fetus, and poor fetal outcome may result despite a good outcome in the mother. Venom has been shown to induce uterine contractions in animal models, and placental abruption has been reported. Most published reviews and case series of snakebite in pregnancy include nonnative envenomations, limiting the applicability of findings to patients envenomated by native species. In one review of 30 envenomations during pregnancy, maternal death occurred in 10% of cases while 43% of fetuses died [90]. A more recent review of the worldwide English literature regarding pregnancy and snakebite identified 213 cases. Maternal death rate was found to be 4.2%, with a fetal death rate of 19.2%. Deaths occurred in all three trimesters. Of those with bites by North American species, there was one fetal death and one neonatal death [91]. The fetal death was reported in a small case series in 1966, in which the mother was described to be hypotensive and tachycardic on presentation following the bite by an unknown species of snake. A dead fetus was delivered at 9 weeks gestational age 24 h after the bite [92]. The neonatal death, reported in 1984, occurred 6 weeks after the bite in a 28-week pregnant patient who presented with hypotension after a copperhead envenomation and was treated with epinephrine. The baby had evidence of intracranial hemorrhage at birth and died at 4 days of age [93]. A more recent poison center database review of native snake envenomations included 65 pregnant

patients, most of whom were reported to have copperhead bites. Eleven patients were treated with antivenom and there were no deaths. Long-term outcomes were not reported [1].

Pregnant patients who present with a snake envenomation should receive supportive care and fetal monitoring. Neither CroFab nor Anavip have been studied in pregnant women and both are classified as Category C drugs [73, 87]. CroFab has been given to pregnant women without evidence of harm. Due to the potential morbidity to both mother and fetus resulting from snake envenomation, pregnant women should receive antivenom if they meet usual indications for treatment. Signs of fetal distress or uterine contractions considered to result from the envenomation should also prompt treatment with antivenom (LOE II-3).

Following treatment with antivenom, pregnant women should be monitored very closely for late hemotoxicity. This recommendation is based on a recent, as-of-yet unpublished case of massive vaginal hemorrhage and first-trimester fetal loss that occurred in the setting of late coagulopathy with afibrinogenemia and normal platelet count. The author recommends monitoring fibrinogen levels and platelet counts every 1–2 days during the first 7–10 days after antivenom treatment, until clearly stable without a trend toward abnormal values. Due to the risk for spontaneous abortion in the setting of hypofibrinogenemia or afibrinogenemia, the author recommends treatment of late coagulopathy with antivenom, even if platelets are within the range of normal.

Indications for ICU Admission

Evidence of envenomation with local progression
Significant coagulopathy, thrombocytopenia, or bleeding
Systemic symptoms, such as hypotension or shock
Neurotoxic findings
Need for antivenom treatment

Key Points

1. Presenting clinical findings following rattlesnake envenomation rarely represent peak severity of illness
2. Frequent clinical reassessment is important, as envenomation is a dynamic process, which may appear to stabilize and then subsequently worsen and require additional therapy
3. Antivenom therapy should be administered as early as possible to prevent worsening local findings and reduce morbidity
4. Thrombocytopenia and coagulopathy should be treated with antivenom, not with blood products, unless these findings are resistant to antivenom therapy and patient is bleeding
5. Fasciotomy should not be performed unless compartment pressure is measured and elevated
6. Following treatment with antivenom and prior to hospital discharge, it is important to give patients clear information regarding risk of late hematologic toxicity, potential for bleeding, and importance of continued laboratory monitoring up to 2 weeks post antivenom

Criteria for ICU Discharge

Envenomation no longer progressing
Further need for antivenom not anticipated

Snakebites can cause life-threatening injuries, sometimes requiring intensive care. The most important snakebites occurring in Latin America are provoked by species of the family Viperidae (*Bothrops*, *Crotalus*, and *Lachesis*) and Elapidae (genus *Micrurus*). Viperid venoms induce prominent local tissue pathology, which may lead to permanent sequelae and systemic disturbances associated with coagulopathies, bleeding, hemodynamic alterations, and acute kidney injury. Elapid snake venoms, and South American rattlesnake venoms, induce neurotoxic manifestations associated with paralysis of various muscles, including respiratory muscles. Treatment of envenomation is based on parenteral administration of antivenoms. Severely envenomed patients need an adequate life support therapy such as treatment of shock, assisted ventilation, and renal therapy replacement.

Epidemiological Aspects

Snakebite envenomation constitutes a relevant public health problem in Central and South America, where an estimated number of 70,000 cases occur every year [1]. However, owing to underreporting of this neglected tropical disease in the region, it is likely that the actual magnitude of snakebite envenomation is higher.

As in other parts of the world, this disease affects mainly people living in impoverished agricultural settings, including native communities. It affects predominantly young males, but accidents are reported in people of all ages. A large proportion of snakebites occur while people are performing agricultural work, being therefore a rural occupational health problem. The majority of snakebites occur in the feet (about 50% of the cases), followed by hands (about 30%), implying that basic preventive measures should include the use of shoes and exercising care when touching the ground with the hands. The number of bites varies depending on the time of year, with higher incidence during the rainy season, probably in association with the onset of agricultural duties; natural disasters, particularly flooding, increase the risk of snakebites. Weather fluctuations,

including El Niño Southern Oscillation (ENSO), are known to affect the incidence of snakebites [2]. Indigenous communities are particularly vulnerable to this disease due to a high incidence, and to the difficulties in accessing health centers.

It is estimated that the total number of snakebites occurring every year in Central and South America are approximately 4,000 and 50,000 cases, respectively [1, 3]. In Central America, the highest number of cases and incidence is in Panama, with around 2,000 bites per year [1]. In South America, Brazil reports 26,000–29,000 cases per year [4], Venezuela 7,000, Colombia 4,000, and Peru, Ecuador and Bolivia around 1,500 cases per year each (see [1] and references therein), although the actual numbers are likely to be higher. Regarding fatalities, the mortality rate per 100,000 population described for some countries are: Costa Rica: 0.02–0.15 [5]; Panama, 0.5 [1]; Venezuela, 0.1–0.2 [6]; Brazil, 0.05 [4]; Ecuador, 0.05 [7]. The case fatality rate in Brazil is around 0.42%, and in Costa Rica is about 0.5%. Snakebite envenomation results in permanent physical and psychological sequelae in an unknown number of affected people, thus generating significant personal and social suffering, an aspect of this disease which has not been appropriately documented.

Snake Species of Highest Medical Relevance

The vast majority of snakebites occurring in Latin America are caused by species of the family Viperidae, particularly of the genus *Bothrops* spp. [8, 9]. In Brazil, for instance, about 70% of snakebite cases are inflicted by species of *Bothrops*. The most important species are *Bothrops asper* (Fig. 1a) in Central America and northern parts of South America and *B. atrox* (Fig. 1b) in the Amazonian regions of South America. Other species of *Bothrops* spp. which cause a high number of cases in South America are *B. jararaca* (Fig. 1c), *B. alternatus*, *B. moojeni* (Fig. 1d), and *B. neuwiedi*. On the other hand, envenomation by various subspecies of the South American rattlesnake *Crotalus durissus* (Fig. 2) can be of high severity [9, 10], with a

Fig. 3 *Lachesis muta* from Brazil (Photograph by Giuseppe Puorto)

reported case fatality rate in Brazil of 0.98% (as compared to 0.39% in the case of *Bothrops*) [11]. Envenomation by *Lachesis* spp. (Fig. 3) in Central and South America are scarce, although they usually are highly severe [12].

Coral snakes (genera *Micrurus*, *Leptomicrurus* and *Micruroides*) (Fig. 4) are the representatives of the family Elapidae in the Americas, together with

the pelagic sea snake, *Pelamis platura*. Coral snakes are responsible for 1–2% of snakebites in Central and South America, with the following species being responsible for the majority of these cases: *Micrurus nigrocinctus* in Central America and *M. mipartitus*, *M. corallinus*, *M. frontalis*, *M. lemniscatus*, and *M. spixii* in South America. Bites by *Pelamis platura* are extremely rare.

Pathophysiology: Mechanism of Action of Venoms

Venoms of the majority of species of the family Viperidae: These venoms are characterized by a high content of hydrolytic enzymes, mostly zinc-dependent metalloproteinases, phospholipases A_2 , and serine proteinases [13]. Metalloproteinases and phospholipases A_2 are largely responsible for the drastic local tissue pathology characteristic of envenomation by viperid species, i.e., hemorrhage, myonecrosis, dermonecrosis, blistering, lymphatic vessel damage, and extracellular matrix degradation [14]. These pathological alterations are associated with a prominent inflammatory reaction characterized by edema and pain.

Myonecrosis is due to a direct disruptive effect of myotoxic phospholipases A_2 on the integrity of the plasma membrane of skeletal muscle cells, in addition to the consequences of local ischemia generated by the vascular alterations induced by the venom [14]. Hemorrhage, in turn, is caused by the alterations induced by venom metalloproteinases on the basement membrane of capillary blood vessels, resulting in extravasation [15]. Alterations in the skin, i.e., dermonecrosis and blistering, are mostly caused by metalloproteinases, which also cause widespread degradation of the extracellular matrix.

Upon systemic distribution of venom components, metalloproteinases cause systemic hemorrhage, by damaging the structure of capillary vessels in various organs, including the brain. Systemic bleeding is potentiated by the alterations

induced by venom components in the hemostatic system. Procoagulant metalloproteinases (prothrombin activators and factor X activators) and serine proteinases (“thrombin-like enzymes”) induce the formation of microclots, with the consequent consumption of clotting factors, especially fibrinogen. This causes the alteration of clotting tests, such as the whole blood clotting time, prothrombin time, and partial thromboplastin time [16]. This defibrinogenating effect is associated with activation of the fibrinolytic system, with the generation of fibrin-degradation products. In addition, viperid venoms have components, such as disintegrins, that affect platelet aggregation. These alterations in coagulation and in platelet function contribute to the bleeding initiated by the disruption of microvessels by the action of metalloproteinases [17]. As a consequence of the systemic bleeding, hemodynamic alterations often ensue, which might end up in a cardiovascular shock.

Viperid snake venoms also affect the kidney, often causing acute kidney injury. This effect is of multifactorial origin, as it is due to (a) the action of nephrotoxic components; (b) the ischemia resulting in the kidney as a consequence of hemodynamic alterations; (c) the toxicity induced by the presence of hemoglobin and myoglobin in the kidney tubules; and (d) the action of metalloproteinases in the basement membrane of the glomeruli.

Venoms of South American rattlesnakes:

The venoms of South American rattlesnakes of the species *Crotalus durissus* have a mechanism of action which greatly differs from those of the

majority of viperid species. These venoms are characterized by a high concentration of the neurotoxic and myotoxic phospholipase A₂ heterodimeric complex “crotoxin.” This toxin provokes neuromuscular paralysis through a presynaptic mode of action, thus resulting in paralysis of various muscles, including respiratory muscles. In addition, crotoxin is a potent myotoxin, inducing generalized muscle damage, i.e., rhabdomyolysis. In turn, the massive release of muscle-derived proteins, such as myoglobin, exerts a deleterious effect in the kidneys, generating acute kidney injury [10]. In addition, the venoms of subspecies of *C. durissus* induce clotting disturbances, i.e., defibrinogenation [18], through the action of a thrombin-like serine proteinase.

Venoms of coral snakes: The venoms of coral snakes (*Micrurus* spp.) contain high amounts of postsynaptically acting neurotoxins of the three-finger family (α -neurotoxins), together with phospholipases A₂ [19]. The main effect induced by these toxins is a neuromuscular blockade owing to the high-affinity binding of α -neurotoxins to the nicotinic cholinergic receptor at the motor end plate of muscle fibers. This results in clinical manifestations of descending flaccid neuromuscular paralysis, which may eventually end in paralysis of respiratory muscles. Some of these venoms also possess neurotoxic phospholipases A₂ which affect neuromuscular transmission at the presynaptic level. *Micrurus* spp. venoms also contain myotoxic phospholipases A₂; however, owing to the relatively low amount of venom that these snakes are able to inject in a bite, systemic myotoxicity seldom develops in coral snakebites.

Clinical Presentation

In most cases of snakebite, the snake responsible is not captured for identification; even when it is captured, there is rarely an expert on hand to make the correct identification. Therefore, the diagnosis is typically based on the victim's history and especially on clinical manifestations and laboratory tests results. Consequently, careful history-taking and physical examination are essential, together with ordering the appropriate laboratory tests. In addition, some snakebites are so-called dry bites (i.e., those that result in no envenomation).

Antivenom should be administered only to patients who present with clinical and/or laboratory manifestations of envenomation.

The severity of envenomation depends on several factors, including the amount of venom injected, the time from the bite to the administration of antivenom, the anatomical area affected (bites on the head or neck are usually more severe), and the medical history, as well as the size of the victim (the consequences of a bite can be more severe in children). In addition, variations in venom composition observed within and between species, attributable to ontogenetic and geographic factors, can influence the severity of envenomation.

***Bothrops* and *Bothrops*-Like Snakes (Including *Agkistrodon*, *Atropoides*, *Bothriechis*, *Bothriopsis*, *Bothrocophias*, and *Porthidium*)**

The so-called *Bothrops* group includes the genera *Atropoides*, *Bothrops*, *Bothriechis*, *Bothriopsis*, *Bothrocophias*, and *Porthidium*, although snakes of the *Bothrops* genus itself are responsible for more bites than are those of the other genera. Although there is little information about snakebites caused by *Agkistrodon*, *Atropoides*, *Bothriechis*, *Bothriopsis*, *Bothrocophias*, and *Porthidium*, the available data indicate that envenomation by species belonging to any of these genera provokes manifestations similar to those observed in individuals with *Bothrops* envenomation. Therefore, the term “*Bothrops* syndrome” will be used in order to refer to such manifestations, collectively [20–23].

Clinical Presentation

Local Effects

After a *Bothrops* bite, there is a small extent of bleeding at the venom inoculation site, where there can also be edema, pain, redness, and bruising (Fig. 5). Less frequently, there is persistent bleeding at the bite site. The pain can initially be mild, becoming more severe as the edema increases. Bruising at the site can be minimal in the first hours after the bite and more pronounced

Fig. 5 Clinical features of *Bothrops* envenomation 3 h after bite. (a) Fang puncture marks are visible on hand. (b) Swelling and bruising in right arm

Fig. 6 *Bothrops* envenomation. (a) Serous-hemorrhagic blister at the bite site 1 day after snakebite. (b) Serous blisters at bitten limb 2 days after the snakebite

on the following day. The extent of edema increases during the first 24 h following the bite and can involve all of the affected extremity, reaching the trunk in some cases. Serous-hemorrhagic or hemorrhagic blisters (Fig. 6) can appear during the first 24 h after the bite [24–27].

Systemic Effects

The most common systemic manifestation in *Bothrops* syndrome is coagulopathy, i.e., blood

incoagulability [26]. However, in envenomations caused by *Bothriechis lateralis*, *Porthidium nasutum*, *P. ophryomegas*, or *P. lansbergii*, coagulopathy might not occur because the venoms of those snakes do not have procoagulant components and do not induce defibrin(ogen)ation in vivo [28, 29]. There can be ecchymosis (local and regional) (Fig. 7) and spontaneous bleeding (Fig. 8) (such as gingival bleeding, epistaxis, and hematuria). Although cases of

Fig. 7 *Bothrops* envenomation: patient was bitten in right hand; ecchymoses are observed in both arms

Fig. 8 Gingival bleeding 5 h after *Bothrops* snakebite

severe bleeding (hematemesis, hemoptysis, rectal bleeding, metrorrhagia, subcapsular hepatic hematoma, and central nervous system bleeding) have been reported, such cases are rare (Table 1). Even less common are reports of hypotension and shock, which can be due to bleeding and fluid loss into the third space, induced either directly by the action of venom in the microvasculature or by the release of inflammatory mediators [20, 24, 25, 30–33].

Snakebites caused by young snakes of some species can produce minimal local alterations (Fig. 9), although such bites often result in significant coagulopathy. That can be attributed to ontogenetic variations among venoms [34–37].

Complications

Local

Local complications of *Bothrops* syndrome include infection (Fig. 10) (cellulitis, abscesses, and fasciitis), necrosis (Fig. 11), and compartment syndrome (due to swelling, which can compress the neurovascular bundle). The frequency of amputation is low (Table 1).

Infection: The tissue damage resulting from envenomation predisposes to infection. Infection is caused by bacteria present in the mouth, fangs, or venom of the snake and is more common in moderate-to-severe envenomation. The organisms most often isolated from abscesses secondary to *Bothrops* envenomation are gram-negative bacteria, such as *Morganella morganii*, *Proteus mirabilis*, *Proteus rettgeri*, *Pseudomonas aeruginosa*, *Acinetobacter calcoaceticus*, *Escherichia coli*, and *Klebsiella pneumoniae*. Gram-positive bacteria (*Staphylococcus aureus*, group D streptococci, and *Streptococcus viridans*) and anaerobic bacteria have also been isolated [38–41].

Necrosis: Necrosis resulting from *Bothrops* envenomation is associated with bites from adult snakes, bites occurring in certain anatomical areas (necrosis is more common in the fingers), and with the use of tourniquet [35, 42, 43].

Compartment syndrome: Compartment syndrome is a less common complication [38, 42] that usually occurs early (in the first 24 h after the snakebite). It can evolve to severe outcomes, such as loss of muscle mass as well as neuropathy and amputation. The diagnosis of compartment syndrome in snakebite victims is difficult, because the usual manifestations of snake envenomation, i.e., pain and swelling, can mimic those of compartment syndrome. Careful clinical examination and serial reexamination is required. Tissue pressure should be measured when possible in order to avoid misdiagnosis and unnecessary surgery. The combination of clinical findings consistent with compartment syndrome and increased intracompartmental pressure is ideal for establishing the diagnosis and for more precisely determining whether fasciotomy is indicated [44, 45].

HVB Hospital Vital Brazil, NA not available, AKI acute kidney injury, +: the manifestation is observed, but the frequency is not available

Systemic

Systemic complications of *Bothrops* syndrome include acute kidney injury (AKI) and septicemia. Chronic renal failure is uncommon. Reversible posterior leukoencephalopathy was reported in a patient bitten by a *Bothrops asper* [46]

AKI: The frequency of AKI in *Bothrops* syndrome varies from 1.6% to 38.5%. The pathophysiology of *Bothrops* envenomation-induced AKI involves several factors, such as release of inflammatory mediators, hemodynamic

changes, disseminated intravascular coagulation, intravascular hemolysis, and a possible direct action of venom toxins in the kidneys. It is more common in older age groups and is associated with a longer time from snakebite to antivenom therapy. The most common change in renal structure is acute tubular necrosis. Cases involving bilateral cortical necrosis, acute glomerulonephritis, or interstitial nephritis with mesangial proliferation have also been reported [47, 48].

Septicemia: In *Bothrops* syndrome patients, septicemia is rare. It can occur secondary to infections in the subcutaneous tissue at the bite site [30, 38]. In patients subjected to invasive procedures, septicemia can be due to nosocomial infection, such as ventilator-associated pneumonia and central venous catheter-associated bloodstream infection.

Fig. 9 *Bothrops* envenomation. Patient bitten by a young *Bothrops* snake in toe presented with unclottable blood 3 h after the bite, and minimal alterations a bite site

Fig. 10 Soft tissue infection secondary to *Bothrops* envenomation, 4 days after snakebite

General

Deaths after bites from *Bothrops* group snakes are associated with AKI, central nervous system bleeding, shock, or sepsis [20, 30, 47, 49, 50]. There is little information in the literature about sequelae of infection, necrosis, and fibrosis. In general, victims are not monitored over the long term, and it is therefore not possible to evaluate late sequelae. Table 1 shows clinical data related to the occurrence and complications of snakebites from different *Bothrops* species.

Laboratory Tests

Ancillary exams can show alterations caused by or complications secondary to *Bothrops* envenomation.

Complete Blood Count

On admission, a complete blood count (CBC) for a patient with *Bothrops* syndrome can reveal elevated hemoglobin levels and hemoconcentration, secondary to increments in vascular permeability. However, some *Bothrops* syndrome patients present with bleeding or massive hemolysis, resulting in anemia. In such patients, the leukocyte count can be normal or elevated (indicating leukocytosis). There can also be neutrophilia (absolute or relative) and thrombocytopenia [53].

Biochemistry

In *Bothrops* syndrome patients with AKI, urea and creatinine are elevated. Levels of creatine kinase (CK) can also be elevated, which can be attributed to the myotoxic effects of the venom of some

Fig. 11 Necrosis after *Bothrops* envenomation. (a) Necrosis of finger tip 13 days after snakebite. (b) Necrosis of left foot 15 days after snakebite

Bothrops species, to infection or to compartment syndrome [44]. In addition, there can be intravascular hemolysis, which may result in high levels of lactate dehydrogenase (LDH) and indirect bilirubin in serum.

Blood Coagulation Tests

In patients with *Bothrops* syndrome, whole blood clotting time (WBCT), prothrombin time (PT), and activated partial thromboplastin time (APTT) can be normal or abnormal (prolonged), and some patients present with a complete loss of coagulability. In addition, *Bothrops* syndrome provokes fibrinogen consumption, together with elevated levels of fibrin degradation products (FDPs) and D-dimer [54, 55]. Coagulation tests are quite important, because they facilitate the diagnosis and inform decisions regarding treatment. Such tests should be ordered on admission, as well as at 12 and 24 h after antivenom administration. It should be kept in mind that venoms of several species of the genera *Porthidium* and *Bothriechis* do not affect clotting tests.

Urine Analysis

The results of the urinalysis of *Bothrops* syndrome patients can be normal. However, some patients present with hematuria, proteinuria, or both.

Arterial Blood Gas Analysis

Arterial blood gas analysis can reveal metabolic acidosis in patients with AKI or sepsis.

Others

In some cases, ultrasonography, computerized tomography, or nuclear magnetic resonance imaging is needed in order to diagnose complications and to determine the appropriate treatment strategy.

Lachesis

Clinical Presentation

Envenomations by snakes of the genus *Lachesis* present pathophysiological manifestations similar to those described for *Bothrops* envenomations,

and the clinical features can be indistinguishable. There have been few reports of *Lachesis* snakebites and most of the cases described have been severe. If the animal responsible is not captured for identification, the diagnosis can be made on the basis of vagomimetic signs and symptoms, together with epidemiological information. As in *Bothrops* envenomation, changes can occur at the bite site (local effects) and elsewhere (systemic effects) [12, 38, 56–59].

Local Effects

Victims of *Lachesis* snakebite present edema, which can be extensive, at the bite site. The site can also evolve to pain, bruising, and blisters.

Systemic Effects

The reported systemic effects of *Lachesis* snakebite include coagulopathy and spontaneous bleeding, such as epistaxis and macroscopic hematuria. Vagomimetic manifestations, such as nausea, vomiting, sweating, abdominal pain, diarrhea, hypotension, and shock, can also be observed. Although such manifestations strengthen the diagnosis, their absence does not rule out the possibility of *Lachesis* envenomation.

Complications

There have been few reports of *Lachesis* envenomation. Despite such limited information, there is indication that the complications are similar to those observed in *Bothrops* envenomations.

Local

Local complication of *Lachesis* snakebite includes skin infection and necrosis. Some victims develop compartment syndrome [38, 56].

Systemic

Victims of *Lachesis* snakebite can evolve to AKI [38] and sepsis. In patients who eventually died from *Lachesis* envenomation-induced sepsis, gram-positive and gram-negative bacteria (*Clostridium* spp. and *E. coli*, respectively) have been isolated [56].

Laboratory Tests

CBC

In cases of *Lachesis* envenomation, the CBC can be altered. Patients might develop leukocytosis, neutrophilia, and thrombocytopenia [12, 59].

Biochemistry

In *Lachesis* bite victims who develop AKI, urea and creatinine levels are elevated. CK levels are slightly elevated [12].

Blood Coagulation Tests

In *Lachesis* envenomation, as in *Bothrops* syndrome, the WBCT, PT, and APTT can be normal or abnormal (prolonged), and some patients present with a complete loss of coagulability. In addition, *Lachesis* envenomation reportedly causes fibrinogen consumption, as well as high levels of FDPs and D-dimer [12].

Crotalus

South America Versus Central America

The reported consequences of bites from rattlesnakes of the genus *Crotalus* in South America are mainly neuromuscular blockade and rhabdomyolysis, which may cause AKI. In contrast, envenomation by *Crotalus* snakes in Central America is characterized by effects similar to those of *Bothrops* envenomation.

Clinical Presentation in South America

Local Effects

In South America, the local signs and symptoms at a *Crotalus* bite site are less intense than those observed in cases of *Bothrops* and *Lachesis*. Victims of a *Crotalus* bite in South America present with edema, erythema, and pain – in most cases near the bite site (Fig. 12a).

Systemic Effects

Most of the alterations observed in *Crotalus* envenomation in South America are systemic. Initial symptoms are blurred vision and a “heavy

Fig. 12 Clinical features of South American *Crotalus* envenomation: (a) The bite site with fang puncture marks; (b) Bilateral palpebral ptosis; (c) Dark urine due to myoglobinuria

eyelids” feeling. Patients can evolve to palpebral ptosis (Fig. 12b), diplopia, mydriasis, anisocoria, mandibular ptosis, weakness, and tremors. Paralysis of the muscles of the soft palate causes dysphagia. In severe cases, patients progress to weakness and prostration, some developing respiratory failure secondary to paralysis of the respiratory muscles [10, 60–64]. In addition, there can be signs and symptoms of rhabdomyolysis, such as myalgia and dark urine (Fig. 12c) (due to myoglobinuria) [10, 65–67]. Bruising and bleeding (such as gingival bleeding) can occur, resulting from coagulopathy caused by the procoagulant enzymes of the venom, although those effects are less common.

General

In *Crotalus* envenomation in South America, the systemic effects are more pronounced than are the local effects. In one report of envenomation from the bite of a young *Crotalus* snake, the only alteration observed was coagulopathy, which was not accompanied by neuromuscular or myotoxic manifestations [68]. In mild cases, neuromuscular symptoms can appear late, approximately 12 h

after the bite. Therefore, in cases of *Crotalus* snakebite, it is necessary to monitor victims closely and for a prolonged period. In the days following the snakebite, victims report symptoms such as altered taste and smell. The neuromuscular effects can persist for days or weeks after antivenom therapy.

Complications

Local

In cases of *Crotalus* envenomation in South America, infection at the bite site can occur but does so infrequently [69]. In one reported case, a *Crotalus* bite victim developed compartment syndrome, which was managed without fasciotomy and evolved without sequelae [70].

Systemic

After *Crotalus* snakebite in South America, the most common complication is AKI due to rhabdomyolysis. In 10–29% of cases, the victim develops AKI [48]. Risk factors for developing AKI include delayed administration of

antivenom, plasma CK activity $>2,000$ U/L on admission, and being below 12 years of age [71]. Patients with severe neuromuscular manifestations can develop aspiration pneumonia and atelectasis. Death results from renal failure and respiratory failure. The case fatality rate is higher among patients with delayed treatment, receiving specific antivenom therapy more than 6 h after the bite [11].

Laboratory Tests

CBC

In victims of *Crotalus* snakebite in South America, the CBC can reveal a normal leukocyte count or leukocytosis, together with absolute or relative neutrophilia. Thrombocytopenia is not common [10, 60].

Biochemistry

After *Crotalus* snakebite in South America, musculoskeletal injury leads to increases in the serum levels of CK, aspartate aminotransferase, and LDH. The CK level can be extremely high, proportional to the severity of envenomation, and increases early (in the first 2 h after the bite), peaking after approximately 24 h. The dynamics of the increase in aspartate aminotransferase is similar to that of CK, whereas the LDH level rises more slowly, peaking between 48 and 72 h after the bite [72]. Serum concentration of urea, creatinine, potassium, phosphorus, and uric acid are elevated in the presence of AKI. Although calcium levels are decreased in the early stage of *Crotalus* envenomation-induced AKI, hypercalcemia can occur in the recovery phase of rhabdomyolysis, due to mobilization of calcium deposited in the injured muscle.

Blood Coagulation Tests

Coagulopathy is seen in 40–50% of patients with *Crotalus* envenomation in South America. The WBCT, PT, and APTT can be normal or abnormal (prolonged). In addition, the fibrinogen level can be low; elevated levels of FDPs and D-dimer can be observed [18].

Urine Analysis

Among victims of *Crotalus* snakebites in South America, those who do not develop AKI show normal urine analysis findings. Those who develop rhabdomyolysis can present with myoglobinuria.

Arterial Blood Gas Analysis

In patients with *Crotalus* envenomation-induced AKI, metabolic acidosis can be observed. Those with respiratory failure that is not properly managed, in terms of the ventilation strategy, can develop hypoxemia, hypercapnia, and respiratory acidosis.

Clinical Presentation of *Crotalus* Bites in Central America

Local Effects

Bites from *Crotalus simus* snakes (found in Mexico and Central America) provoke local changes such as swelling and pain. In severe cases, those changes can affect the entire limb. Bruising and blisters can also be observed. Local necrosis is reported in rare cases [73, 74].

Systemic Effects

In cases of *Crotalus* envenomation in Central America, bleeding – including epistaxis, gingival bleeding, hematemesis, and hematuria (macroscopic and microscopic) – has been reported [73, 74]. Victims of *Crotalus* snakebite in Central America can present with nausea and vomiting, although neuromuscular manifestations are rare. Coagulopathy with fibrinogen consumption are often observed [74]. The venom of young *C. simus* snakes exhibits a toxicological profile similar to that of the venom of young snakes of *Crotalus* species in South America, in terms of neurotoxicity, as well as in terms of the potential to induce rhabdomyolysis and coagulopathy [75]. Nevertheless, it is not known whether such effects occur in humans bitten by young *C. simus* individuals, as neurotoxic envenomings by *Crotalus simus* have not been described in Central America.

Elapidae Family

Clinical Presentation

Local Effects

In most cases of bites from snakes of the genus *Micrurus* (family: Elapidae), there is no significant alteration at the bite site, other than the bite marks and erythema. Most patients report mild local pain or paresthesia. However, there has been at least one report of severe pain in the bitten limb [76].

Systemic Effects

The main systemic alterations seen in *Micrurus* snakebite victims result from neuromuscular blockade. Manifestations of neurotoxicity include blurred vision, diplopia, palpebral ptosis (Fig. 13), mydriasis, anisocoria, mandibular ptosis, dysphagia, and weakness. In severe cases, the patient can develop dyspnea and respiratory failure due to paralysis of the respiratory muscles. Manifestations such as dizziness, nausea, vomiting, excessive salivation, and generalized paresthesia are also observed. Localized mild myalgia can occur, and, less frequently, there can be myalgia in areas distant from the bite [73, 76–79].

Bites from the so-called yellow-bellied sea snake (*Pelamis platura*) are rare, and there have been no reports describing the clinical manifestations. However, experimental studies of *P. platura* venom suggest that it causes neurotoxic manifestations similar to those observed in cases of bites from true coral snakes [80].

Fig. 13 Bilateral palpebral ptosis 4 h after bite by *Micrurus* snake

Complications

Elapidae snakebite victims with severe neuromuscular manifestations can develop aspiration pneumonia. Such individuals can also develop atelectasis.

Laboratory Tests

CBC

Patients with *Micrurus* envenomation present with leukocytosis. In one case report, an individual bitten by a *Micrurus lemniscatus helleri* in the Peruvian Amazon developed thrombocytopenia [76].

Biochemistry

In victims of *Micrurus* snakebite, CK levels can be slightly elevated.

Blood Coagulation Tests

Micrurus snakebite victims do not present with coagulopathy.

Arterial Blood Gas Analysis

Among patients with *Micrurus* envenomation, those who progress to respiratory failure and do not receive proper ventilatory support can develop hypoxemia and respiratory acidosis.

Non-Front-Fanged Colubroid Snakes (NFFC snakes)

The bites of some species of snakes previously classified in the family Colubridae (*sensu lato*) (such as *Boiruna*, *Philodryas*, and *Thamnodynastes*; all now in Family Dipsadidae, Subfamily Xenodontinae) can occasionally evolve to intense local effects such as swelling, pain, and bruising. However, such bites do not generally lead to systemic envenomation and therefore should not cause manifestations requiring intensive care [81–84]. These snakes, and their bites, are discussed in more detail in ► Chap. 124, “Non-Front-Fanged Colubroid Snakes.”

Treatment for Venomous Snakebites in Central and South America

Most of the knowledge about treatments for snakebites in Central and South America comes from accumulated clinical experience; there have been very few controlled studies of such treatments. Therefore, recommendations regarding the appropriate clinical approach are devised by consensus among regional authorities.

Antivenom Therapy

The only scientifically valid treatment for snake envenomation is parenteral antivenom administration. It is a heterologous product composed of either whole immunoglobulins (IgG) or immunoglobulin fragments (F(ab')₂ or Fab) obtained from the plasma of horses or sheep hyperimmunized with snake venoms. Antivenoms used in Latin America are either whole IgG or F(ab')₂ products. In Central and South America, the number of vials to be administered must be in accordance with the guidelines of the manufacturing laboratory and the guidelines generated in each country, because there is variation among countries

and producers in terms of the amount of venom neutralized per milliliter of antivenom. The number of vials of antivenom administered varies according to the severity of the symptoms, which is evaluated on the basis of the clinical manifestations on admission. However, the severity criteria can vary by country. Table 2 shows the severity criteria used for snakebite envenomation in Brazil.

In envenomations characterized by local manifestations at the bite site, such as those from snakes belonging to the genera *Agkistrodon*, *Atropoides*, *Bothrops*, *Bothriechis*, *Bothriopsis*, *Bothrocophias*, *Porthidium*, or *Crotalus* in Central America, or *Lachesis*, the edema can continue to progress, even after the administration of antivenom, for up to 24 h after envenomation. That is because the edema and pain are consequences of the release of endogenous inflammatory mediators after venom inoculation.

Regarding antivenom therapy, certain aspects must be born in mind:

- Antivenom should be administered only to patients with manifestations of envenomation; some bites (“dry bites”) do not lead to envenomation and antivenom should not be used in these cases.

Table 2 Specific treatment for snakebites in Brazil according to the severity of the clinical presentation on admission^a

Snake genus	Clinical presentation
<i>Bothrops</i>	Mild: local edema in 1 or 2 of the 5 segments defined ^b ; cutaneous or mucosal bleeding; normal or altered coagulation test results
	Moderate: edema in 3 or 4 segments; light bleeding; normal or altered coagulation test results
	Severe: edema in all 5 segments; severe hemorrhage, hypotension/shock; normal or altered coagulation test results
<i>Crotalus</i>	Mild: barely perceptible myasthenic facies; no myalgia or dark urine; normal or altered coagulation test results
	Moderate: evident myasthenic facies; myalgia and dark urine; normal or altered coagulation test results
	Severe: evident myasthenic facies; intense myalgia and dark urine; difficulty breathing; normal or altered coagulation test results
<i>Lachesis</i>	Local signs and symptoms; occasional bleeding; no vagal manifestations
	Intense local signs and symptoms; occasional bleeding; evident vagal manifestations
<i>Micrurus</i>	All cases considered potentially severe

^aBased on the 1998 Brazilian National Ministry of Health Guidelines for the Diagnosis and Treatment of Animal Envenomation [85]

^bDivision of the upper and lower limbs into segments: segment 1 = foot/hand; segment 2 = distal half of the leg/forearm; segment 3 = proximal half of the leg/forearm; segment 4 = distal half of the thigh/upper arm; segment 5 = proximal half of the thigh/upper arm

- The antivenom should be administered intravenously.
- The number of ampules or vials required will vary according to the severity of the symptoms assessed on admission.
- Patients should receive the antivenom specific to the genus or family of snake that caused the envenomation.
- The antivenom can be diluted in 5% glucose or in saline solution. Although the dilution is typically between 1:5 and 1:10, the total volume to be administered should be evaluated on a case-by-case basis, taking into account patient weight and the presence of comorbidities that limit the administration of fluids.
- The antivenom should be administered in 30 min to 1 h; antivenom administration can be initiated slowly and increased gradually.
- In patients who present a hypersensitivity reaction to the antivenom during its administration (early adverse reaction), the infusion of the solution should be temporarily suspended and the hypersensitivity reaction should be treated in accordance with the type and intensity of the signs and symptoms. Epinephrine (adrenaline) is the drug of choice to treat anaphylaxis [86]. After treatment of the early reaction, antivenom therapy should be reinitiated, although the antivenom should be more diluted and infused more slowly.
- In cases of bites from snakes whose venom causes coagulopathy (*Bothrops*, *Lachesis*, and *Crotalus*), coagulation tests should be performed 12–24 h after antivenom administration, in order to assess the treatment. If there is no improvement of coagulopathy after 12 h (i.e., if blood still does not clot), the following possibilities should be considered: the antivenom was administered inappropriately (misdiagnosis of the type of envenomation); the quantity of antivenom administered was insufficient (error in the assessment of severity); or the antivenom was stored improperly or is out of date. However, in most cases in which the coagulation test results did not improve after antivenom administration, the etiologic diagnosis has been found to be incorrect.
- In patients with snake envenomation, it is important to achieve good peripheral venous access for antivenom administration. The venous access should not be obtained on the bitten limb, especially in cases of bites by snakes whose venom causes edema. In patients with coagulopathy, venous access via the peripheral jugular vein should be avoided because of the risk of loss of access and of hematoma, which can impair breathing by causing extrinsic airway compression.

Ancillary Treatment

Resuscitation

For snakebite victims requiring resuscitation, the airway-breathing-circulation approach should be employed. All vital signs should be checked.

Fasting

During antivenom administration, snakebite victims should fast, because there is a risk of nausea and vomiting as manifestations of hypersensitivity to the antivenom. After antivenom administration, the clinical condition of the patient should be evaluated before the decision to allow the consumption of food is made. Patients bitten by *Crotalus* and *Micrurus* snakes, whose venoms cause neuromuscular paralysis, should be carefully assessed before restarting an oral diet, given the possible progression of muscle paralysis to difficulty in swallowing and respiratory failure.

Fluid Resuscitation

Adequate crystalloid fluid resuscitation is necessary for proper hydration, the target hourly urine output being 1–2 mL/kg of body weight (BW) for children and 30–40 mL for adults. In individuals bitten by snakes belonging to one of the South American genera of *Crotalus* whose venom causes rhabdomyolysis, reversing the intravascular volume depletion is one of the most important measures to prevent AKI, because it restores proper renal perfusion and increases urine flow, preventing the formation of myoglobin pigment casts and the consequent tubular obstruction. In the setting of rhabdomyolysis, the goal of fluid

resuscitation is to maintain a urine output of 200–300 mL/h. Care should be taken to avoid volume overload, especially in children and individuals with heart disease or anuria [87].

Vasoactive Drugs

Snakebite victims who develop hypotension and do not respond to volume expansion with crystalloid solution should receive vasoactive drugs.

Atropine

In *Lachesis* envenomation, atropine administration should be considered if the patient develops bradycardia with hemodynamic instability.

Analgesia

To control the pain resulting from a snakebite, dipyrone, paracetamol, or opioids can be administered as necessary. The use of nonsteroidal anti-inflammatory drugs should be avoided.

Diuretics

In patients with snakebite envenomation who develop oliguria despite being adequately hydrated, a diuretic such as furosemide can be prescribed to stimulate urine flow. Diuretic administration can thus facilitate the management of volume overload in patients with AKI.

Urinary Alkalinization

In *Crotalus* snakebite victims who develop severe rhabdomyolysis, raising the urinary pH to above 6.5 can reduce toxicity and increase myoglobin solubility in the renal tubules. However, although urinary alkalinization is a common intervention in the management of rhabdomyolysis, there is little clinical evidence of its benefit [87]. The use of this measure should be avoided if the patient does not present a level of urine output sufficient to avoid alkalosis.

Mannitol

In *Crotalus* snakebite envenomation, which can lead to rhabdomyolysis, mannitol can be considered as an osmotic diuretic for the prevention of AKI, although its routine use is not recommended [87]. To avoid fluid overload and circulatory congestion, mannitol should be used only after the

blood volume has been corrected and the appropriate urine output has been achieved. The recommended dose of mannitol is a bolus of 0.5 g/kg BW per hour, followed by 0.1 g/kg BW per hour, in 0.45% saline.

Acetylcholinesterase Inhibitors

If a *Micrurus* snakebite victim develops respiratory failure and requires assisted ventilation, the use of acetylcholinesterase inhibitors such as neostigmine or edrophonium hydrochloride should be considered as a means of reversing the neuromuscular effects. Experimental studies and isolated reports support the use of acetylcholinesterase inhibitors for the treatment of bites from *Micrurus* snakes whose venom has predominant postsynaptic activity [88]. To prevent the muscarinic effects of acetylcholine (especially bradycardia and hypersecretion), patients can be injected intravenously with atropine – 0.5 mg for adults and 0.02 mg/kg per dose (maximum, 0.5 mg per dose) for children – prior to intravenous administration of neostigmine (0.05 mg/kg BW) or edrophonium hydrochloride (0.25 mg/kg BW for children and 10 mg for adults). Normally, the response is rapid, and a single dose is sufficient in some cases. If neuromuscular manifestations recur, the regimen should be repeated every 2–4 h or the acetylcholinesterase inhibitor should be administered as a continuous infusion (starting at 25 µg/kg BW per hour), the dosage being titrated according to the clinical response. If there is no response to this treatment, the acetylcholinesterase inhibitor should be discontinued.

Antibiotic Therapy

In cases of secondary infection after snakebite, as often occurs in *Bothrops* and *Lachesis* snakebite victims, the recommended treatment is with broad-spectrum antibiotics that are active against gram-negative bacteria (especially *Morganella* spp.), gram-positive bacteria, and anaerobic bacteria. Such antibiotics include chloramphenicol, clindamycin (in combination with ceftriaxone or ciprofloxacin), and ampicillin in combination with sulbactam. Whenever possible, the treatment regime should be reevaluated through the use of cultures and sensitivity testing.

Surgical Procedures

In snakebite victims, any abscess should be drained in a timely manner and areas of necrosis should be debrided. If there is suspicion of compartment syndrome, the patient should be carefully evaluated in order to determine whether fasciotomy is indicated. The use of fasciotomy should be limited to cases in which subfascial pressure remains elevated (>30 mmHg) or, more precisely, if the compartment perfusion pressure (mean blood pressure minus intracompartmental pressure) is ≤ 30 mmHg.

Use of Blood Products

Transfusion of fresh frozen plasma, cryoprecipitate, or platelets should not be used as a substitute for antivenom administration, in the correction of hemostatic disorders; spontaneous bleeding ceases a few hours after the initiation of antivenom administration. However, when there is a need to carry out invasive or surgical procedures after antivenom administration but prior to the reversal of coagulopathy, blood products can and should be used.

Renal Replacement Therapy

In some patients with AKI, dialysis should be considered.

Mechanical Ventilation

Patients with snake envenomation who present with neuromuscular manifestations, such as those with *Crotalus* or *Micrurus* envenomation, can occasionally progress to impaired respiratory function. Such patients require endotracheal intubation and mechanical ventilation.

Postural Drainage

If there is edema at the site of a snakebite, the affected limb should be elevated. However, in cases of compartment syndrome, that practice should be reevaluated.

Tourniquet Use

Tourniquets should not be applied in cases of snakebite, especially in those caused by snakes whose venom leads to intense local inflammation

(*Agkistrodon*, *Atropoides*, *Bothrops*, *Bothriechis*, *Bothriopsis*, *Bothrocophias*, *Porthidium*, or *Crotalus* in Central America, or *Lachesis*). If a tourniquet has been applied, it should be removed slowly and carefully, in order to avoid the abrupt release of vasoactive factors and the consequent shock [89].

Parenteral Medication

Medications should not be injected at the bite site. In cases of snakebites that might provoke coagulopathy (*Bothrops*, *Lachesis*, and *Crotalus* bites), intramuscular injections should also be avoided until clotting alterations are corrected.

Invasive Procedures

In snakebite victims, unnecessary invasive procedures, such as the use of a central venous catheter or urinary catheter, should be avoided, especially in those who have developed coagulopathy.

Tetanus Prophylaxis

If warranted on the basis of the vaccination history, the tetanus immunization status of patients with snake envenomation should be updated. In addition, the need for anti-tetanus serum or immunoglobulin should be evaluated. When tetanus prophylaxis is indicated, it should be administered after normalization of coagulopathy (typically 24 h after antivenom administration), in order to prevent hematoma formation.

Follow-Up Care

An individual who has been bitten by a venomous snake will require appropriate physical therapy in order to avoid contractures and deformities. Immobilization should be interrupted by frequent periods of gentle exercise, progressing from passive to active and including stretching, if indicated. Some patients might need to be followed up by a plastic surgeon, orthopedist, physiatrist, physical therapist, or occupational therapist. Furthermore long-term psychological consequences experienced by victims of snakebite are not known and needs investigation.

Spiders are ubiquitous arthropod predators, common in all habitats occupied by humans, including modern urban environments. They may achieve high population densities – greater than one million per hectare [1]. Their primary interaction with humans is beneficial, as they act as biologic controls for arthropod pests, notably insects. Their medical interaction with humans is relatively minor, in comparison, but still significant because of the extent of exposure to risk.

Extent of Spider Bite as a Medical Problem

There are no accurate figures on which to gauge the global extent of spider bite. Logically, given the large numbers of spiders living in proximity to humans, bites should be common, but because most spiders are small and unlikely to inject more than miniscule quantities of venom compared with average human body mass, most bites could be expected to be trivial. Many spiders coexisting with humans are moderate to large in size, however, and at least a few of these are known to cause significant envenoming [2]. When spider bite is considered by the human population and a venue is provided to seek advice about bites, experience in Australia suggests that bites are reported frequently. Spider bite has been the most common or second most common cause of calls to Australian poison information centers at least since 1995, usually

eclipsing every pharmaceutical class, including paracetamol/acetaminophen, until recent years [2]. In the USA spider bite has been a less frequent cause of calls to poison centers [3], though in the 1950s spider bite was reported to cause six to seven deaths per year [4] and a higher rate of significant bites than reported to poison centers is suspected [3]. In contrast, in Switzerland the reported incidence is just 1–10 bites/100,000 population, with mostly mild effects and universally good outcomes in studied cases [5]. When consciousness of spider bite is lower or the expectation that health services can assist is not present, it can be expected that the recorded incidence of cases will be lower, underestimating the extent of spider bite incidence. However, recent data from the USA appears to indicate that spiderbite results in more fatalities than snakebite in that country (70 vs. 59 in the 9 year study period), though detail on what type of spider and the cause of death is lacking [6]. This indicates spiderbite is not a universally benign phenomenon.

Medically Important Spiders

A few spider groups or effects of spider bite stand out as clinically important (Table 1) [2, 3]. Many other spiders occasionally or rarely have been reported to bite humans, although mostly with minor effects (Table 2). The former groups, few in number but global in extent, dominate the medical problem posed by spider bite. In Brazil,

despite a vast spider fauna, virtually all medically important spider bites are due to just three groups: banana spiders (genus *Phoneutria* – phoneutrimism (Fig. 1)), recluse or violin spiders (genus *Loxosceles* – loxoscelism (Fig. 2)), and widow spiders (genus *Latrodectus* – latrodectism (Fig. 3)). In North America, widow spiders and recluse spiders also are responsible for most significant bites. In Europe, Africa, Asia, and Australia, widow spiders are an important source of spider bite, whereas recluse spiders also cause significant problems in parts of Africa, Europe, and possibly Australia. In Australia, widow spider envenoming occasions more use of antivenom than all other causes of envenoming combined (including snakes), a remarkable finding, given that continent’s diverse, common, and highly toxic fauna. Another group of spiders also is of great relevance in Australia: the funnel-web spiders (*Atrax* and *Hadronyche* spp. (Figs. 4 and 5)), the most toxic of all the world’s spiders (not to be confused with North American funnel-web spiders, which are quite different and of minor importance medically).

Spider Taxonomy

Spider taxonomy is complex, and differentiating to species generally requires great expertise and the use of a microscope because it frequently involves detailed examination of male external genital organs [2]. Many spider species are yet to

Table 1 Spider groups of major medical importance

Spider group	Common name	Distribution	Clinical effects
Mygalomorphae			
<i>Atrax</i> and <i>Hadronyche</i> spp.	Funnel-web spiders	Australia	Excitatory neurotoxic effects, catecholamine storm, potentially lethal
Araneomorphae			
<i>Latrodectus</i> spp.	Widow spiders	Global	Latrodectism: excitatory neurotoxic effects, pain, malaise, rarely lethal
<i>Phoneutria</i> spp.	Banana spiders	Brazil	Phoneutrimism: excitatory neurotoxic effects, pain, malaise, rarely lethal
<i>Loxosceles</i> spp.	Recluse spiders	Global	Loxoscelism: local tissue necrosis, rarely major systemic effects, shock, hemolysis, DIC, occasionally fatal
Nonspecific	Various	Global	Necrotic arachnidism: spider bite resulting in local necrosis

DIC disseminated intravascular coagulation

Table 2 Spiders known to cause significant effects on biting humans^a [1–3, 7–21]

Family	Scientific name	Common name	Distribution
Mygalomorphs			
Ctenizidae	<i>Aganippe</i>	Trapdoor spider	Australia
	<i>Arabantis</i> spp.	Trapdoor spider	Australia, East Indies
	<i>Bothriocyrtum</i> spp.	Trapdoor spider	California
	<i>Dyarcycops</i>	Trapdoor spider	Australia, New Zealand
	<i>Ummidia</i> spp.	Trapdoor spider	North and Central America
Hexathelidae	<i>Atrax</i> spp. and <i>Hadronyche</i> spp.	Funnel-web spider	Australia
Theraphosidae	<i>Harpactirella</i>	Trapdoor spider	South Africa
	<i>Pamphobetus</i> spp.	Tarantula	South America
	<i>Aphonopelma</i> spp.	Tarantula	North America
	<i>Dugesia</i> spp.	Tarantula	North America
	<i>Selenocosmia</i>	Tarantula	East Indies, India, Australia
	<i>Lasidora</i> spp.	Caranguejeiras	South America
	<i>Poecilotheria</i> spp.	Ornamental tree spiders	India, Sri Lanka
	<i>Lampropelma nigerrimum</i>	Tarantula	Asia
	<i>Pterinochilus murinus</i>	Tarantula	Africa
	<i>Eumenophorus</i> spp.	Tarantula	Africa
	<i>Stromatopelma</i> spp.	Tarantula	Africa
Dipluridae	<i>Trechona</i> spp.	Funnel-web spider	Central and South America
Actinopodidae	<i>Missulena</i> spp.	Mouse spider	Australia
Araneomorphs			
Agelenidae			Europe, North America
	<i>Hololena</i> spp.	Agelinid spider	North America
Araneidae	<i>Araneus</i> spp.	Orb weaver	Worldwide
	<i>Argiope</i> spp.	Orb weaver	Worldwide
	<i>Neoscona</i> spp.	Orb weaver	Worldwide
			Worldwide
Clubionidae	<i>Chiracanthium</i> spp.	Sac spider	Worldwide
	<i>Liocranoides</i>	Running spider	Appalachia and California
	<i>Trachelas</i> spp.	Sac spider	North America
Ctenidae	<i>Cupiennius</i> spp.	Banana spider	Central and South America, West Indies
	<i>Elassoctenus harpax</i>	Hunting spider	Australia
	<i>Phoneutria</i> spp.	Banana spider	Central and South America
Desidae (Amaurobiidae)	<i>Ixeuticus (Badumna)</i> spp.	House spider	New Zealand, Southern California
Dysderidae	<i>Dysdera</i> spp.	Dysderid	Worldwide
Filistatidae	<i>Filistata</i> spp.	Hackled band spider	Worldwide
Gnaphosidae	<i>Drassodes</i> spp.	Running spider	Worldwide
	<i>Lampona</i> spp.	White-tailed spider	Australia, New Zealand
	<i>Herpyllus</i> spp.	Parson spider	North America
Loxoscelidae	<i>Loxosceles</i> spp.	Recluse spiders	Worldwide
Lycosidae	<i>Lycosa</i> spp.	Wolf spiders	Worldwide
	<i>Hippasa</i> spp.	Indian wolf spiders	Indian subcontinent
Miturgidae	<i>Miturga</i> spp.	Miturgid spiders	Australia, New Zealand
Oxyopidae	<i>Peuceetia</i> spp.	Lynx spider	Worldwide

(continued)

Table 2 (continued)

Family	Scientific name	Common name	Distribution
Salticidae	<i>Phidippus</i> spp.	Jumping spider	Worldwide
	<i>Holoplatys</i> spp.	Jumping spider	Australia
	<i>Mopsus</i> spp.	Jumping spider	Australia
	<i>Thiodina</i> spp.	Jumping spider	Americas
Siariidae	<i>Sicarius</i> spp.	Six-eyed crab spider	Africa
Sparassidae	<i>Heteropoda</i> spp.	Huntsman spiders	Worldwide
	<i>Isopoda</i> spp.	Huntsman spiders	Australia, New Guinea, East Indies
	<i>Olios</i> spp.	Huntsman spiders	Americas, Australia
Theridiidae	<i>Latrodectus</i> spp.	Widow spiders	Worldwide
	<i>Achaeranea tepidariorum</i>	Grey house spider	Worldwide
	<i>Steatoda</i> spp.	False black widow	Worldwide
Thomisidae	<i>Misumenoides</i> spp.	Crab spider	Americas
Zoridae	<i>Diallomus</i> spp.	Zorid spider	Australia

^aFor most (except those listed in Table 1), generally minor clinical effects only

receive formal scientific description and naming. Scientists undertaking this task are few in number. Although previously described common spiders were thought to belong to a single taxon, more

recent research indicates that numerous species exist. This profusion of species and difficulty in assigning accurate nomenclature has ensured that the medical literature on spider bites and spider venom research is replete with inaccuracies that muddy understanding of this field.

Mygalomorphs

Order Mygalomorphae, together with the Araneomorphae (see later), currently contains most living spider species. Mygalomorphs are considered more ancient or primitive than araneomorph spiders, but neither group is recent, for spiders date back hundreds of millions of years. The basic distinguishing features are shown in Fig. 6. Mygalomorphs exist in a wide array of habitats globally, varying from small to large sized species, but in general these are mostly

Fig. 3 Female black widow spider, *Latrodectus mactans* (Copyright © Dr. Julian White, 2016)

Fig. 5 Female Australian tree funnel-web spider, *Hadronyche formidabilis* (Copyright © Dr. Julian White, 2016)

Fig. 4 Male Australian Sydney funnel-web spider, *Atrax robustus* (Copyright © Dr. Julian White, 2016)

large terrestrial or occasionally arboreal spiders, living most of their lives in web retreats, often a burrow in the ground, usually with traplines radiating from the retreat, such that the spider rarely ventures far from the retreat except to mate. It is generally the male that explores in search of the female, which is at least one reason bites by mygalomorphs are more likely to be caused by male spiders. In some of the most deadly species, notably the Sydney funnel-web spider, the male has venom more toxic to humans than that of the female. This phenomenon is not universal,

because in some other funnel-web spiders, the female venom is as toxic as that of the male.

Araneomorphs

Araneomorph spiders, order Araneomorphae, are more diverse in numbers, range of species, size, shape, geographic distribution, and effects on humans. Their fang anatomy also is more diverse than mygalomorphs but can be distinguished from the latter moderately easily in most cases (see Fig. 6). Most medically important spiders fall into just three groups of araneomorphs: widow spiders, recluse spiders, and banana spiders.

Spider Venoms

As with most other venoms, spider venoms are usually complex mixtures of substances, with the most potent toxins being peptides or more complex proteins and generally falling within the class of neuroexcitatory toxins, with similarities in effect, if not structure, to the more potent scorpion toxins [2]. There is an important significant divergence from this characterization – the necrotoxins – which are best characterized from recluse spider venoms but possibly are present much more widely than recluse spiders are.

Fig. 6 Diagrammatic representation of the anatomic differences between mygalomorph spiders and araneomorph spiders

Effects of Spider Bite

The clinical effects of spider bite in humans fall into several broad categories. In most cases and for most spider species, the effects of a bite on humans are negligible. In the few cases and for the few spiders capable of inflicting injury on humans, two distinct patterns are seen: neuroexcitatory envenoming and locally necrotic envenoming [2, 3]. In general, these two patterns do not coexist in the same spider. Even for spiders capable of causing major envenoming in humans, the rate of dry bites is high and probably exceeds 80%. There are many factors affecting what symptoms are likely from a spider bite (Table 3).

Local Effects of Envenoming

For most spider species capable of causing a noticeable effect in humans, local pain, usually short-lived, sometimes accompanied by erythema or mild swelling is the only likely effect. Fang marks may not be apparent and are most likely to be direct punctures, not the minimal lacerations seen with some snakebites (caused by fangs dragging through the skin). Double punctures are likely, mostly close together, depending on the size and type of spider.

A few species cause more notable local effects, such as formation of distinct lumps or even blistering. Fewer still occasionally cause significant local tissue injury. Foremost among the latter are

Table 3 Spider and victim factors affecting the likely symptoms of a spider bite

Specific factors	Likely effect or influence
Spider-related factors	
Species of spider	Most species of spider are harmless to humans
Sex of the spider	For several species known to be toxic to humans, a specific sex is more toxic (e.g., for widow spiders, only the female is likely to envenom humans, whereas for Australian funnel-web spiders, both sexes are toxic, but only the male has caused fatalities)
Maturity of the spider	Usually only adult spiders are clinically toxic to humans
Individual spider	As with most other venomous animals, there is likely to be variation in venom components and toxicity between individuals of the same species and even for a given individual spider over time, depending on maturity, when venom was last expelled, and season
Quantity of venom injected	This varies greatly
Attack position	For any given species of spider, fang length is within a narrow range depending on the size of the spider, and angle of attack when biting a human victim determines how effectively the fangs may penetrate skin and inject venom
Gut secretions	For many species of spider, the fang tips at rest are close to the mouth parts, and it is possible that digestive secretions from the mouth may enter the wound caused by the act of biting a human with the fangs, with consequent effects being due to these digestive secretions and the venom. While this may be important in causation of some clinically significant local effects of spider bite, it remains unproven
Bacterial flora on the fangs, mouth parts, and adjacent structures	The act of biting a human with a fang has the potential to contaminate the wound with any bacteria on adjacent areas of the spider, with the consequence that clinically significant local effects of the bite may be due at least in part to secondary infection introduced by the act of biting. The bacterial flora on relevant areas of spiders is not known. However, evidence to date indicates that secondary infection following spider bite is uncommon to rare, with the possible exception of ulcerative lesions caused by some recluse spider bites
Number of times the spider bites the human victim	Multiple bites in general are more likely to result in clinically significant effects
Length of time the spider takes to make each bite	A brief glancing strike in general is less likely to result in clinically significant effects than would occur if the spider “hangs on,” taking some time to bite. This is only relative, however, because the toxicity of the spider concerned is of greater importance
Human victim–related factors	
Age of the human victim	In general, a child or an elderly adult is more likely to suffer clinically significant consequences of a spider bite than a normal healthy adult. This principle is not universal, however. In our experience in Australia with latrodectism (envenoming by widow spiders), often large, muscular men seem worst affected by the bite and require the most antivenom to reverse envenoming
Size of the victim	In general, the larger the human, the more body mass to dilute any venom and its effects; small children are usually at greater risk (but note above caveat for latrodectism)
Position of the bite	There are some areas of the body where it would be more difficult for a spider to penetrate the skin successfully and inject venom, such as where the skin is thicker or callused. For bites causing local tissue injury, bites on peripheral or dependent areas, such as the feet and lower legs, are more likely to result in problems
Preexisting health of the victim	Preexisting disease may make the results of any spider bite worse than might be expected in healthy people. Of concern are diseases either decreasing natural immunity to infection or reducing the capacity of local tissue at the bite site to withstand venom effects (e.g., peripheral vascular disease)
Allergic reactions	Individual inappropriate immune responses to venom may result in a far more clinically significant bite than otherwise would occur. This may be an anaphylactic-type reaction, which appears rare with spider bite, or a more localized reaction, which may result in significant and continuing tissue damage. A classic example of atypical local reaction to a bite is the development of pyoderma gangrenosum, which has been associated with loxoscelism

After White et al. [2]

the recluse spiders (see ► Chap. 130, “*Loxosceles Spiders*”), whose venom contains toxins that cause tissue necrosis, directly or indirectly [2, 3]. This process may begin soon after the bite but clinically is apparent only after several hours, whereas impending necrosis may take days to become discernible. There is growing, if generally inconclusive, evidence that spiders other than recluse spiders occasionally may cause tissue necrosis [22–28]. This area has engendered much speculative “science,” such as the speculation, raised to the level of “fact” by some, concerning tissue necrosis caused by spiders such as the wandering spider, *Tegenaria agrestis* in North America, and the white-tailed spider, *Lampona cylindrata* in Australia [24–28]. For these latter two species, at least, the current evidence indicates they do not cause necrotic bites. For a few other spiders, notably *Chiracanthium* spp., a reputation for occasionally causing necrotic bites appears to have limited supporting evidence [2, 22, 29].

General Effects of Envenoming

Some species capable of inflicting short-term local pain or erythema also may cause general systemic symptoms, manifested as one or more of the following: headache, malaise, nausea, vomiting, abdominal pain, flulike illness, or dizziness. The toxins responsible for such symptoms are not characterized, and the effects are generally not indicative of a particular species and so have little diagnostic value. The symptoms generally resolve over a matter of a few hours, less commonly over 1–2 days.

Neuroexcitatory Effects of Envenoming

Major neurologic effects generally are limited to species with potent neuroexcitatory toxins in their venom (widow spiders, banana spiders, Australian funnel-web spiders) [2, 3]. Their presentation depends principally on the type of spider. The details of each of these groups are found

in ► Chaps. 131, “Widow and Related *Lactrodectus* Spiders,” and ► 129, “Australian Funnel Web Spiders.” However, a growing list of other spiders, predominantly Mygalomorphs in the tarantula family (Theraphosidae), have been reported as causing medically significant, though nonlethal, envenoming that appears to be related to neurotoxicity [2, 7–9, 16]. A number of Theraphosid spider venoms have been examined and shown to contain potent peptide toxins, often with neurotoxic actions. As more cases are reported and more species have venom studied, it is likely the list of medically important Mygalomorph spiders will expand, but so far there is no evidence to indicate they will approach the overall medical significance of the already established spider groups of major importance, noted earlier.

Hemolytic and Related Effects of Envenoming

A subset of patients with loxoscelism after recluse spider bite develop major, potentially life-threatening systemic envenoming, in addition to the local necrotic effects typical of these spiders [2]. These systemic effects include hemolysis, disseminated intravascular coagulation, renal failure, shock, liver failure, multiorgan failure, and death. Death occurred in 30% of cases in the early loxoscelism literature from Chile, and fatalities still occur even in North America, although now rarely. More detailed discussion may be found in ► Chap. 130, “*Loxosceles Spiders*” [2].

Other Effects of Envenoming

For spiderbite overall, considering the many species recorded as at least occasionally biting humans, the predominant symptom, if any symptoms develop, is local short-lived pain at the bite site. Some larger spiders, such as huntsman (Araneomorphae: Sparassidae), have fangs large enough to cause distinct puncture marks which may result in local short-term bleeding [17].

A few tarantula spiders (Mygalomorphae: Theraphosidae) may cause irritation of skin and mucosal membranes through active shedding of abdominal hairs, the best known example being the Mexican orange kneed tarantula, *Brachypelma smithi*, popular in the pet trade [2].

First Aid for Spider Bite

Spider bite generally requires no first aid other than reassurance. For most of the remaining cases, use of local cold pack application is sufficient. Widow spiders require either no first aid or use of a cold pack [2] (Grade III recommendation). First aid is impractical for recluse spider bites because the bite is generally not apparent until many hours later [2]. Banana spider bites may respond to cold packs [2].

Australian funnel-web spiders are quite different from the other spiders; funnel-web spider bite is potentially lethal, and correct first aid not only can delay envenoming but also can reduce the extent of envenoming [2]. The reason for the latter is an observation that this venom is destroyed if restricted to the bite site for a prolonged period [30]. The correct first aid is use of a pressure bandage and immobilization by splint ("PBI"; see ► Chap. 122, "Australian and Pacific Snakes") [2, 30] (Grade III recommendation). Given that death may occur, at least in children, in 10 min after the bite, the importance of correct and prompt first aid is obvious.

Diagnosis of Spider Bite

The diagnosis of spider bite is sometimes straightforward, more commonly shrouded in some doubt, and frequently tenuous or uncertain. This situation relates to the ease with which a bite may occur without the culprit's being seen and the delayed nature of envenoming by certain species, notably species causing necrotic arachnidism, such as the recluse spiders. For certain species or groups of spiders, even in the absence of an identifiable specimen or reliable description of the

culprit, a diagnosis may be made with some confidence because of the distinctive nature of presentation and symptoms and signs [2, 31].

Significant envenoming by widow spiders classically is associated with a witnessed bite by a widow spider or a bite causing at least some immediate local discomfort, followed by the development of progressively more severe local pain, often with local sweating [2, 31]. The pain may move in focus from the bite site proximally to involve limbs or trunk, again often associated with sweating and hypertension, nausea, and malaise. The rate of progression in severity and area involved is variable, from 1 h to more than 24 h. Trunk pain may involve the abdomen or thorax and may mimic acute abdomen or myocardial ischemic pain. The diagnosis becomes more certain if treatment with sufficient amounts of appropriate antivenom results in clear resolution of the symptom complex.

Significant envenoming by an Australian funnel-web spider typically is associated with immediate pain, and the spider is usually seen and sometimes may need to be pulled off the victim [2, 31]. Systemic symptoms ensue rapidly, first manifested in 5–20 min by tingling around the lips and twitching of the tongue, rapidly followed by signs of catecholamine storm, with piloerection, hypersalivation and hyperlacrimation, hypertension, abdominal pain, nausea, and progressive severe pulmonary edema, with secondary hypoxia and impaired conscious state. The progression from first symptoms to lethal outcome may take 20–30 min or may take 1–3 h or occasionally longer. Without adequate antivenom therapy, death is likely.

Significant envenoming by a Brazilian banana spider typically is associated with a witnessed bite with marked local pain, with edema, erythema, and frequently sweating [2]. Systemic features include tachycardia; hypertension; nausea and vomiting; increased sweating and salivation; priapism in boys; and, in severe cases, pulmonary edema, cardiac arrhythmias, and shock. A fatal outcome is rare.

Significant envenoming by recluse spiders typically presents hours or days after the presumed

bite, which is usually not witnessed because the bite is painless and frequently occurs at night while the patient is asleep [2]. A spider is rarely available for identification. Even in most published series, a spider was positively identified in less than 10% of cases. In the first 24 h, the bite area becomes painful, erythematous, then mottled with hemorrhagic areas, often associated with systemic symptoms, such as fever, generalized erythema, and malaise. The diagnosis is usually apparent by the second day. After 4–7 days, an area of necrosis develops, with often severe pain. Less commonly in South American cases, rarely elsewhere, a severe systemic illness develops, with intravascular hemolysis, thrombocytopenia, disseminated intravascular coagulation, renal failure, potentially multiple organ failure, and death [2].

Treatment of Spider Bite

Treatment of spider bite most often consists of reassurance and short-term follow-up to exclude development of secondary infection [2]. For the few spiders capable of causing significant envenoming (e.g., widow spiders, Australian funnel-web spiders, Brazilian banana spiders, recluse spiders), treatment sometimes may be more significant, but even for these species most cases ultimately prove to be minor.

Approach to Treatment

Effective treatment of spider bite relies on early diagnosis of the likely culprit – in particular, defining if it is probably one of the few spider species of medical importance [2, 31]. If it is likely to be a potentially dangerous species, such as an Australian funnel-web spider, assessment is urgent, and specific treatment must be instituted as soon as systemic envenoming is apparent. For most other spiders, however, even widow spiders, it is practical to observe for a period before starting definitive treatment because many cases are minor, and a delay does not endanger life in most instances.

Specific Treatment: Antivenom

When available, antivenom is the most effective treatment for systemic envenoming; this is particularly true for significant bites by Australian funnel-web spiders, where major envenoming is likely to prove lethal without antivenom [2] (See ► Chap. 129, “Australian Funnel Web Spiders”). Widow spider bites rarely prove lethal but can cause prolonged and unpleasant symptoms, justifying antivenom therapy [2]. In Australia, where widow spider bites are frequent, antivenom is used routinely and has been considered effective and reasonably safe [2, 31]. Recently the RAVE II trial which was a double blind randomized control trial of IV antivenom versus placebo has cast doubt on the effectiveness of antivenom in latrodectism, resulting in some toxicologists no longer recommending this antivenom treatment [32]. However, there are some uncertainties about the validity of both the trial and its interpretation, particularly since it provided an answer (that antivenom is ineffective) that is at odds with more than 50 years experience with this antivenom in Australia [33]. Further, it failed to find an effective alternative treatment, noting that 70% of patients failed to gain significant symptom relief from analgesia alone, which is the current only alternative treatment. The author of this chapter has been treating Australian widow spider bites for nearly 40 years and has seen many cases respond rapidly and fully to antivenom, often after other treatment options have been tried and failed. It is therefore this author’s opinion that the RAVE II study alone should not result in change in treatment practice but that independent confirmation of the RAVE II study results should be undertaken (Grade III recommendation). Given that previous research has indicated an antivenom raised against one widow spider species is likely to be effective against other species of *Latrodectus* and that an increasing number of case reports, case series and trials have shown effectiveness, to varying degrees, of anti-*Latrodectus* antivenom, it appears the overall body of evidence supports the use of antivenom, despite the RAVE II study [2, 31, 33–44] (Grade I recommendation). Antivenom is used in moderate-to-severe cases of systemic

envenoming by Brazilian banana spiders, particularly in children and the elderly, but these cases represent only a small proportion of medically treated banana spider bites [2, 45–47]. Antivenom against recluse spiders is also available in Brazil, but its effectiveness at preventing necrosis is contestable, with evidence both supporting and refuting effectiveness and frequently patients present too late for antivenom to be likely to be effective [2, 3, 47–53]. Details of specific antivenom treatments for major spider bite may be found in their respective chapters.

Other Treatments

Details of specific nonantivenom treatments for major spider bite, such as loxoscelism, may be found in ► Chap. 128, “Overview of Spider Envenoming.”

Follow-up

All spider bites should be considered for follow-up, but not all require formal arrangements. For most cases, the significant and uncommon risk is secondary infection. Patients should be instructed on what symptoms and signs to look for, indicating such a complication, and to return promptly if these occur. All patients receiving antivenom should be followed, at least by phone call, to check for serum sickness.

Australian funnel-web spiders are arguably the world's most dangerous spiders. As with most spider bites, the bites caused by funnel-web spiders are frequently minor, but in the approximately 10% of cases in which systemic envenoming occurs, the chance of fatality is significant [1]. Even modern interventions of intensive care medicine are insufficient to save a patient with a severe bite; only antivenom therapy is lifesaving in severe cases [2, 3].

Taxonomy and Distribution

The Australian funnel-web spiders of the genera *Atrax*, *Hadronyche*, and *Illawarra* are restricted to Australia, including Tasmania, as are the related mouse spiders of the genus *Missulena* [4–6]. All are mygalomorph spiders (Fig. 1) of the families Hexathelidae: Atracinae (*Atrax*, *Hadronyche*, *Illawarra*) and Actinopodidae (*Missulena*). They are quite distinct from the “funnel-web spiders” of North America. The Australian funnel-web spiders have recently been revised taxonomically, with names assigned to many species previously listed by number [6].

Funnel-web spiders live most of their lives in self-excavated or constructed silk-lined burrows or tubes, with traplines radiating from the entrance. The spider briefly leaves the burrow to catch prey crossing the traplines [5]. For mating to

occur, however, the male must leave the burrow and roam the surrounding area in search of a female. This biologic necessity ensures that males are more likely to interact with humans than female spiders. There is significant sexual dimorphism, with females being slightly larger, more robust, with larger abdomens, and often with different coloration (particularly mouse spiders) than males.

Atrax

Currently there are three recognized species of *Atrax*, the Sydney funnel-web spider, *Atrax robustus* (Fig. 2), *Atrax yorkmainorum*, and *Atrax sutherlandi*. *A. robustus* has caused the most severe bites and fatalities, partly because it is distributed within a major urban conurbation (Sydney and surrounding areas). All three species are restricted to eastern New South Wales (Fig. 3) [3, 4].

Hadronyche

There are 31 species of *Hadronyche*. They are found in eastern Australia from Cape York to Tasmania (Fig. 3). Several *Hadronyche* spp. have caused significant, potentially lethal bites (Table 1; Figs. 4 and 5) [4–6].

Fig. 2 Male Sydney funnel-web spider, *Atrax robustus* (Copyright © Dr. Julian White, 2001)

Illawarra

This recently erected monotypic genus of Australian funnel-web spiders has one species, *I. wisharti*, about which there is very limited information on venom. The information which is available, however, indicates similarities with *Atrax* and *Hadronyche* venoms. It was previously listed as an unnamed species of genus *Hadronyche* (species “20”) and it may be it has similarly toxic venom as other funnel-web spiders [8]. A few bites have been reported, under its previous identity, but none of these had documented clinical effects. Given the small number of reported cases, it is not possible to determine a level of dangerousness, as it is known that even for other funnel-web spider species that have caused fatalities, most bites do not result in detectable systemic envenoming.

Missulena

The mouse spiders, currently with 16 described species, are of uncertain medical importance [9–11], despite the Australia-wide distribution of these common spiders (Fig. 6) [10–12]. They have toxic venom similar to *Atrax* and *Hadronyche*, but there is only one case of significant envenoming in a human, which was nonfatal.

Venom

The venom of funnel-web spiders is a mixture of components, the most important of which is a class of excitatory neurotoxins, similar across species and potentially lethal for humans, but comparatively nontoxic for most other mammals [1, 8, 12]. This latter property has inhibited research and development of an antivenom. These neurotoxins act at voltage-gated sodium channels (Na_v) and are characterized as having an inhibitor cysteine-knot motif. Similar toxins have been isolated from a variety of other spider venoms and some marine venoms. These toxins isolated from funnel-web spiders, and also the related mouse spiders (genus *Missulena*), act on neurotoxin receptor site 3 at the Na_v and appear to inhibit inactivation of the channel, resulting in neurotransmitter release from somatic and autonomic nerve endings.

Atrax

Of the three species of *Atrax*, *A. robustus* venom has been examined in detail [8, 13–15]. The venom of male spiders is approximately seven times more toxic than that of females. The principal lethal component is δ -atractoxin (δ -ACTX; previously named robustoxin) [8, 14], a protein of molecular weight 4854 d, with 42 amino acid residues, four disulfide bridges, and subcutaneous median lethal dose of 0.16 mg/kg in newborn mice.

Hadronyche

The venom of several *Hadronyche* spp. has been examined, most notably *Hadronyche versuta*, with a principal lethal component similar to δ -ACTX, named *versutoxin* [16] (molecular weight 4852 d, 42 amino acid residues, four disulfide bridges, and subcutaneous median lethal dose 0.22 mg/kg in newborn mice). Venom from *H. formidabilis* and *H. infensa* appears similarly toxic, with equivalent toxicity in males and females, in contrast to *A. robustus*. A recent proteomics study of the venom of 18 species of

Fig. 3 Distribution of Australian funnel-web spiders (Copyright © Dr. Julian White, 2001)

Australian funnel-web spiders demonstrated similarities between all species, but also significant intra- and interspecies differences, and between males and females [15].

Missulena

Research has shown some *Missulena* spp. to have venom with δ -ACTX -like components

Table 1 Australian funnel-web spiders known to have caused significant envenoming in humans, based on confirmed bites by identified spiders. Note that this significantly underestimates numbers of mild bites by Sydney funnel-web spiders [7]

Species	Clinical effects	Number of cases with minor/local effects only	Number of cases with mild to moderate effects	Number of cases with severe effects (% of all cases severe)	Number of deaths reported
<i>Atrax robustus</i>	Major systemic envenoming, known lethality	20+	1	22	13
<i>Hadronyche cerberea</i>	Major systemic envenoming, potentially lethal	1	0	7 (88%)	0
<i>Hadronyche formidabilis</i>	Major systemic envenoming, potentially lethal	2	1	7 (70%)	0
<i>Hadronyche infensa</i>	Moderate-to-severe systemic envenoming, potentially lethal	6	6	3 (20%)	? 1
<i>Hadronyche versuta</i>	Moderate-to-severe systemic envenoming, potentially lethal	9	0	2 (18%)	0
<i>Hadronyche nimoola</i>	Mild to moderate envenoming, lethal potential uncertain	4	2	0	0
<i>Hadronyche macquariensis</i>	Moderate-to-severe systemic envenoming, potentially lethal	4	2	2 (25%)	0
<i>Hadronyche venenata</i>	Mild to moderate envenoming, lethal potential uncertain	8	1	0	0
<i>Hadronyche lynabrae</i>	Mild to moderate envenoming, lethal potential uncertain	2	1	0	0
<i>Illawarra wisharti</i>	Mild envenoming, lethal potential uncertain	5	0	0	0
<i>Other unspecified</i>		9	3	0	0
<i>Immature spiders</i>		8	0	0	0

and to be potentially lethal for humans, although no confirmed fatalities are known [17]. The similarities extend to antigenicity because antivenom against *A. robustus* appears likely to be effective against *Missulena* venom [17]. This statement is consistent with the only reported human case of major envenoming by this genus, in which *Atrax*-specific antivenom was reported to be beneficial [18]. An δ -ACTX-like toxin, δ -missulenatoxin-Mb1a (δ -MSTX-Mb1a)

has been isolated from male *Missulena bradleyi* venom [12].

Clinical Presentation

From a clinical perspective, the effects of *Atrax* and *Hadronyche* bites on humans are essentially the same [1, 7]. Because only one case of severe *Missulena* envenoming has been reported, the

Fig. 4 Female tree funnel-web spider, *Hadronyche formidabilis* (Copyright © Dr. Julian White, 2001)

Fig. 5 Male funnel-web spider, *Hadronyche cerberea* (Copyright © Dr. I. Whyte, 2000)

clinical features of significant envenoming from these spiders are uncertain [10, 11, 18].

Atrax

The bite is usually painful, owing to the size of the fangs (5 mm) and the acidic (pH 4.5–5.0) nature of the venom. The spider frequently hangs on. Bite marks are usually present (Fig. 7). In the few cases in which systemic envenoming develops, there may be rapid onset of early

Fig. 6 Male mouse spider, *Missulena insigne* (Copyright © Dr. Julian White, 2001)

Fig. 7 Local appearance of funnel-web spider bite (From Miller et al. [19]. Copyright © Dr. I. Whyte, 2000)

symptoms, such as lip paresthesias and tongue fasciculation. Time from bite to first systemic symptoms may be 10 min, and deaths occurring in less than 1 h are recorded. Soon after onset of first symptoms, there is progression to more severe envenoming, which may include tachycardia, hypertension, hypersalivation and hyperlacrimation, piloerection, increased sweating, nausea, vomiting, abdominal pain, muscle fasciculation, cardiac dysrhythmias, and pulmonary edema. The venom causes a catecholamine storm effect and while atropine + phenoxybenzamine + propranolol largely abolished major envenoming effects in monkeys, allowing them to survive massive venom doses,

urinary catecholamines were still high. Monkeys surviving the initial envenoming phase then developed progressive hypotension with cardiomegaly and pulmonary edema, so quite distinct from the early phase of hypertension, intracranial hypertension, normal cardiac size, and pulmonary edema.

The pulmonary edema is, at least initially, noncardiogenic and therefore is an acute respiratory distress syndrome. It may develop quickly, be more severe, and result in hypoxia and impaired consciousness or coma. Death in this phase is usually secondary to pulmonary edema. The pulmonary edema is considered neurogenic in origin. Should the patient survive this first phase without antivenom therapy, the untreated clinical course may progress to the second phase, in which excitatory effects subside, secretions cease, and hypertension resolves, only to evolve into a progressive and terminal hypotension, apnea, and cardiac arrest.

Hadronyche

The clinical picture for *Hadronyche* spp. is essentially the same as for *Atrax* spp. except that the former spiders are larger and it is possible, although not yet proven, that the chance of envenoming and life-threatening envenoming may be higher [5, 11–13, 19–21]. Virtually all well-documented deaths after funnel-web spider bite were due to *A. robustus*.

Missulena

The clinical picture for *Missulena* bites is partially characterized, based on 40 confirmed bites by five different species [10, 11]. Experimentally, the venom is similar to funnel-web spider venom, with similar toxicity and effects. These spiders are common, however, and many bites have occurred without significant deleterious effects (R. Raven: personal communication, 1994). In nearly all cases there was either no reported effect

or only mild local or systemic effects [10, 11]. The single case of significant envenoming, in a 19-month-old child following a *Missulena bradleyi* bite, appeared similar to that of *Atrax* envenoming, including hypertension, muscle spasms, and loss of consciousness [18]. This case appeared to respond to funnel-web spider antivenom. Because of this case, and in light of the similarity between *Missulena* venom and that of *Atrax* and *Hadronyche* spp., bites by these spiders should be treated with great caution, using a similar approach to managing funnel-web spider bites [1, 7, 10, 11, 22].

Complications

The principal complications of funnel-web spider envenoming relate to the severity of direct venom effects. There may be hypoxic brain damage or other organ damage secondary to the pulmonary edema or cardiopulmonary or respiratory arrest [1, 2, 5]. There is a single case of prolonged status epilepticus after presumed *Hadronyche* bite, initially thought to be organophosphate poisoning (personal record; not published). In this case, there was no response to atropine, but rapid cessation of seizures occurred after administration of intravenous funnel-web spider antivenom (FWSAV) (CSL Limited, Victoria, Australia). By this stage, irreversible, ultimately fatal brain damage had occurred.

Diagnosis

The diagnosis of funnel-web spider bite is made on clinical symptoms and signs or presentation of a funnel-web spider; currently no venom detection is available [1, 22]. Occasionally, patients may present in confusing circumstances, with no history of a bite and apparent exposure to a chemical (notably, organophosphates), which may cause some similar clinical effects. The only known fatality due to

funnel-web spider bite since introduction of antivenom occurred in such circumstances (see above).

History

In most cases, there is a history of a witnessed bite by a funnel-web spider because the spider is large and the bite generally is painful. Although patients often cannot identify a funnel-web spider confidently, these spiders are distinctive, and within their range it is appropriate that all bites by spiders of this appearance (“big black spiders”) be managed initially as funnel-web bites [22]. Conversely, outside the common range of these spiders, other mygalomorph spiders, such as trapdoor spiders (*Aganipe* spp.) and wishbone spiders (*Dekana* spp.), are frequently misidentified as funnel-web spiders. There is no evidence that these species are dangerous to humans, although also no substantial research, such as venom studies, exists to prove that they are harmless. It is important to recognize that the known areas where funnel-web spider bite may occur, documented by cases, is expanding as better case reporting occurs [23].

After establishing that a bite from a possible funnel-web spider has occurred, it is important to determine if systemic envenoming has developed. Major envenoming is obvious, but in initially minor cases, the clinician should determine if there has been any perioral paresthesias, tongue fasciculation, piloerection, or increased sweating or salivation. The presence of any of the aforementioned signs is strongly suspicious of development of significant systemic envenoming.

Examination

The clinician specifically should look for evidence of autonomic stimulation, such as tongue fasciculation; piloerection; increased sweating, salivation, and lacrimation; tachycardia; hypertension; and particularly pulmonary edema.

Laboratory Tests

There are no tests specific for funnel-web spider envenoming. Experimentally envenomed monkeys have developed metabolic acidosis and elevated creatine phosphokinase concentrations [13].

Differential Diagnosis

No other terrestrial venomous animals are likely to cause a syndrome similar to funnel-web spider envenoming. Red back spiders (widow spiders; *Latrodectus hasseltii* [latrodectism]) can cause increased sweating and occasionally piloerection and commonly cause nausea and abdominal pain and hypertension, but they virtually never cause pulmonary edema [1]. Local, regional, or generalized pain is more prominent in most cases of latrodectism. Organophosphate poisoning may result in symptoms and signs similar to funnel-web spider envenoming – classically, tachycardia, hypertension (bradycardia and hypotension are also possible if muscarinic effects predominate), miosis, muscle fasciculation, excessive secretions, bronchospasm, vomiting, diarrhea, urinary incontinence, and occasionally pulmonary edema. The absence of bronchospasm and prominence of pulmonary edema should suggest funnel-web spider envenoming; conversely, the presence of bronchospasm and comparatively mild pulmonary edema (if present at all) should suggest organophosphate poisoning. Organophosphate poisoning is usually associated with a latent period of 1 or more hours between exposure and onset of symptoms.

Treatment

Treatment of funnel-web spider bite should focus on the needs of the few patients who develop systemic envenoming, because this is potentially lethal [22] (Fig. 8). All patients with definite or suspected funnel-web spider bite should be urgently hospitalized and assessed.

Fig. 8 Outline management plan for funnel-web spider bite (Modified from White [33]; and Miler et al. [19]. Copyright © Dr. Julian White, 2001)

At the first sign of systemic envenoming, anti-venom therapy should be started [22] (Grade II-2 recommendation). Most bites prove minor, however, and any patient presenting more than

6 h postbite without symptoms or signs of systemic envenoming is unlikely to develop envenoming subsequently [22] (Grade II-2 recommendation).

Most cases of funnel-web spider bite need no more than a period of observation because the bite is minor. Because late effects occasionally occur, observation is advisable, for at least 4 h from the time of the bite, or if appropriate first aid has been used, from time of removal of first aid [22].

First Aid

The recommended first aid for funnel-web spider bites is the pressure bandage and immobilization technique (PBI; see ► Chap. 122, “Australian and Pacific Snakes”) [22, 24, 25] (Grade II3_ recommendation). In contrast to snake venom, funnel-web spider venom is at least partially destroyed by prolonged immobilization at the bite site; this method not only delays envenoming but also may reduce the extent of envenoming [24, 26]. This technique is especially important given the rapidity of possible envenoming.

Urgent Measures

After stabilization of airway and breathing, good intravenous access is the next priority to allow rapid intravenous antivenom infusion, if indicated.

Antivenom

The only reliably lifesaving treatment in severe envenoming is intravenous antivenom therapy using specific FWSAV [1, 7, 19, 22, 26–31] (Grade II-2_ recommendation). FWSAV is lyophilized rabbit IgG against male *A. robustus* venom. Since its introduction in 1980–1981, there has been only one presumed death after funnel-web spider bite, and in that single case, death was due to late diagnosis not failure of antivenom. FWSAV is unlikely to cause major adverse immediate reactions, such as anaphylaxis, given the catecholamine excess that is characteristic of these envenomations, but serum sickness has occurred in at least one case (out of >50 treated cases) [7].

When to Use Antivenom

FWSAV should be used in all patients with systemic envenoming except patients who present late (>6 h) with no more than mild envenoming that has not progressed over several hours [22]. At the earliest evidence of systemic envenoming, it is appropriate to consider starting antivenom therapy because progression to life-threatening envenoming may be rapid, especially in children.

Dosage

The initial antivenom dose depends on the degree of envenoming. For mild envenoming, the clinician should consider starting with two vials; for more severe envenoming, treatment may be started with four vials [22]. In either case, if the response is incomplete, giving a further two to four vials may be considered after 15–30 min. Even severe cases usually respond to six to eight vials, but occasionally more vials are required; the maximum recorded dose was 18 vials. Readministration is generally prompted by recurrent episodes of pulmonary edema, each time responding rapidly to antivenom, but then recurring several hours later. There is mounting evidence that *Hadronyche* bites may require higher antivenom doses than *Atrax* bites. There are no clinical data on requirements for *Missulena* bites, but a single human case of severe envenoming appeared to respond to antivenom, consistent with experimental findings showing cross protection [10, 32]. The consensus among treatment experts is to keep giving antivenom until response is complete [22]. In a few cases, there is an initial good response to FWSAV, but several hours later the patient relapses with pulmonary edema. Although this situation occasionally may be due to intravenous fluid overload, it is more likely relapsed envenoming, and further antivenom administration is appropriate. One additional vial may be all that is required in such cases. Children require the same dose as adults. FWSAV is freeze dried, so has to be reconstituted. Because of this the usual dilution of liquid antivenom in Australia is generally not used for FWSAV. If you were treating a small child and had to give 18 vials (180 ml) then fluid overload might be an issue if

all given at once, but that is never the case. The starting dose is two to four vials.

Nonantivenom Treatment

In the absence of antivenom, the other therapeutic interventions for a patient with severe envenoming are of limited efficacy. In patients with severe pulmonary edema, intubation with intermittent positive pressure breathing and positive end-expiratory pressure has had some success [2, 3]. If early hypertension and tachycardia are clinically significant, α blockade has been and may be used, but β blockade is thought to be contraindicated [2]. Atropine has proved useful as a means of controlling secretions, as has diazepam as a sedative measure in the ventilated patient. However, it is not known if diazepam is superior to other standard sedating treatments during mechanical ventilation of funnel-web spider envenomed patients.

Special Populations

Pregnant and Breast-Feeding Patients

The mother and fetus may be severely affected by funnel-web spider envenoming, requiring robust antivenom therapy. There are insufficient reported cases to determine fetal prognosis. However, aggressive and appropriate treatment of the mother likely offers the best prognosis for fetal survival.

Pediatric Patients

Children appear to be at higher risk of rapid, severe, even fatal envenoming, requiring a prompt therapeutic response. If you look at a list of known fatalities, 8 of the 13 are children under the age of 15, and 5 of those are 5 years or younger and are the most rapid deaths. They require just as much antivenom as adults, but fluid overload from intravenous therapy is more likely. This situation may pose a diagnostic dilemma as to whether late-

onset pulmonary edema is due to relapsing envenoming or iatrogenic fluid overload. Clinical circumstances may provide the answer, but if in doubt, the treating physician should consider administering more antivenom.

Elderly Patients

The elderly are at increased risk from envenoming and secondary fluid overload.

Follow-Up

All patients receiving antivenom should receive follow-up, at least by telephone, to detect and monitor for development of serum sickness. All patients with even mild systemic envenoming should be monitored closely in an intensive care setting for at least 24 h or at least 12 h from complete resolution of all symptoms and signs of envenoming, whichever is longer.

Loxosceles spiders, known as brown spiders, recluse spider, or violin spiders, are widely distributed in tropical and temperate regions. The envenomation caused by *Loxosceles*, known by loxoscelism, occurs mainly in the Americas, particularly in South America. Bites typically occur when a sleeping person rolls over on a *Loxosceles* spider in bed or while dressing when pressing a hidden spider between flesh and fabric. *Loxosceles* venom is a mixture of toxins consisting of proteins, glycoproteins, and low-molecular-weight peptides. The key components are members of the sphingomyelinase D/phospholipase D gene family, which activate complement, endothelial cells, and epithelial cells, as well as endogenous metalloproteinases, and are involved in the development of skin necrosis and hemolysis. The *Loxosceles* bite can evolve to skin lesions (cutaneous loxoscelism), which can be accompanied by intravascular hemolysis (cutaneous-hemolytic loxoscelism; also known as viscero-cutaneous loxoscelism). In the cutaneous-hemolytic form, acute kidney injury and, less frequent, disseminated intravascular coagulation can occur as complications of intravascular hemolysis. Treatments prescribed for loxoscelism include particularly antivenom, corticosteroids, and dapsone. However, there is no consensus regarding the best treatment for loxoscelism, and the standard treatment varies among the regions of the world where *Loxosceles* bites occur.

Taxonomy of *Loxosceles* Spiders

Spiders are in the phylum Arthropoda (jointed legs), the class Arachnida and further down the taxonomic tree, the order Araneae (spiders), suborder Araneomorphae. The medically important recluse spiders belong to the genus *Loxosceles* (pronounced *locks-AW-seh-leez*, similar to “isosceles” as in the triangle), derived from the Greek language meaning “crooked or slanted legs” for the way the spiders position their legs when at rest. The first *Loxosceles* species was scientifically described in 1820 from circum-Mediterranean specimens and is currently known

as *L. rufescens*. As of the writing of this chapter, there are 114 *Loxosceles* described worldwide [1] with about 60% being named by one luminary American arachnologist [2, 3]. The first North American species (*L. reclusa*) was named in 1940; earlier references to this species used extant European names which may cause confusion when one reads the older American *Loxosceles* medical literature [4].

Spider Description and Biology

The most common appearance of a recluse spider is a rather nondescript brown spider with tan legs and 8–14 mm in body length when mature. Leg spans may be 2–4 cm. Several of the well-known species have a violin-shaped pattern on the dorsal surface of the cephalothorax (the major body part to which the legs attach) and may also be referred to as violin or fiddleback spiders (Fig. 1). Many North American medical publications have cited this marking as a diagnostic feature for identification. Although this pattern may be conspicuous for species such as *L. reclusa* (Fig. 2a) and *L. rufescens*, not all age stages of these species display such a distinct violin shape. Other species [e.g., *L. laeta* (Fig. 2b) in South America, *L. deserta* in the southwestern USA] have coloration which contrasts weakly with the rest of the

Fig. 1 Because of variability in coloration among the many species, the pattern of six eyes arranged in nontouching pairs is a better identification feature than the violin pattern common in several *Loxosceles* species

Fig. 2 The North American brown recluse spider, *Loxosceles reclusa* (a) and the South American spider, *L. laeta* (b)

cephalothorax such that a violin pattern is not readily apparent [5]. In addition, many harmless spiders have darkened patterns that nonarachnologists (including physicians) have misinterpreted as the violin pattern of a recluse spider [5, 6] resulting in misidentification and potentially excessive and incorrect medical treatment. The more reliable feature that should be used for identification is the eye pattern. Most spiders have eight eyes in two rows of four. The recluse spiders have six eyes with a pair of eyes anteriorly and a pair on either side separated by a space (Fig. 1). The recluse spiders are not the only spiders that have this pattern (e.g., spitting spiders of the genus *Scytodes*) but other features should eliminate those six-eyed nonrecluses from consideration.

In addition, recluse spiders have monochromatic legs and fine recumbent hairs on their legs without conspicuous spines. Most Western Hemisphere *Loxosceles* species have a monochromatic abdomen which can vary from a light cream color

to a dark brown depending on the spider's diet so abdominal coloration is a nondiagnostic feature. However, South African species have boldly patterned tan and brown abdomens, looking very different from most of the other species of the genus.

Recluse spiders are nocturnal and in natural conditions are found under rocks and the loose bark of trees. In buildings, they are found in boxes, under tarpaulins, in holes and cracks in building structures, and behind paintings. They are active hunters where they prowl for their prey at night; but they also lay out silk as triplines from the opening of their retreat, waiting at the mouth of the opening for an appropriate sized prey to become entangled. Once prey is entangled, the spider rushes out to subdue it with a toxic bite.

Many *Loxosceles* species of medical importance are considered synanthropic, i.e., they increase in population in association with humans. Other synanthropic animals include rats, pigeons, and cockroaches. Recluse spider

Fig. 3 The distribution of widespread *Loxosceles* spiders in North America

populations can grow to hundreds or thousands in a single structure such as a house in Kansas (USA) where 2,055 *L. reclusa* spiders were collected in a 6-month period [7] and in a Chilean study where 29% of the inspected homes had *Loxosceles* spiders; the five most densely infested homes yielded an average of 163 *L. laeta* specimens [8]. These large populations develop despite the fact that *Loxosceles* spiders typically lay only 30–80 eggs per egg sac and only a few egg sacs during their lifetimes [4]. However, their behavior is such that they are very tolerant of conspecifics so there is little aggression among members of the same species [9, 10] allowing populations to swell.

Although large numbers of *Loxosceles* spiders in a structure would seem to correlate with greater threat of a bite, in the Chilean study mentioned above, no one in the five densely infested homes complained of a loxoscelism event [8], and the family in the Kansas house lived therein 11 years before someone received a probable recluse bite [4, 7].

Geographic Distribution

The greatest concentration of *Loxosceles* species is centered in Mexico and Central America with South America also containing many species

[2, 3]. There are 11 native species in the United States [4] with six having widespread distribution (Fig. 3). The Mediterranean recluse, is native to southern Europe and northern Africa, is a world-wide tramp found in many locations but is not extremely common outside of its indigenous range; one building may become greatly infested but the infestation typically does not spread beyond that structure unless connected by conduits and pipes. In addition, recent research implies that although *L. rufescens* has been considered one species throughout the Mediterranean area, it is actually several closely related cryptic species [11] which may eventually be separated into distinct taxa in future studies.

A dozen or so species occur in Africa although greater scrutiny may result in additional species being named. Some of the African species are found only in isolated caves which may be the ancestral condition and might explain why some *Loxosceles* species will profusely inhabit one building but not nearby structures. Recently taxonomic work has described several species in Asia. In Australia, the Mediterranean recluse lives in an extremely circumscribed distribution around Adelaide but poses only a mild medical threat there [5] especially when one considers the wealth of toxic organisms on that continent.

Epidemiology

In North America, the brown recluse, *L. reclusa*, has the greatest distribution [4, 5] and is the most likely candidate in loxoscelism. In South America, *L. laeta* is widespread through much of the continent [2] and is a considerable health threat as it is the largest of the *Loxosceles* species (being up to 14 mm in body length) and allegedly has the most toxic bite, due to either size or venom chemistry. Other species of widespread medical concern in South America are *L. gaucho*, *L. similis*, and *L. intermedia*, which are found in southern Brazil and Argentina.

Bites typically occur at night when a sleeping person rolls over on a *Loxosceles* spider in bed or in the morning while dressing when pressing a hidden spider between flesh and fabric. The bite is either painless or felt as a small prick of the skin.

Loxosceles bites are most common on the leg (35%), arm (17%), torso (12%), hand (9%), and foot (5%) with only 0.6–1.5% of the bites occurring on the face, neck, buttocks, shoulder, or genitalia [5].

Loxosceles Venom and Its Histopathophysiological Effects

Loxosceles venom is a mixture of toxins consisting of proteins, glycoproteins, and low-molecular-weight peptides [12–17]. The key components are members of the sphingomyelinase D/phospholipase D gene family, which activate complement, endothelial cells, and epithelial cells, as well as endogenous metalloproteinases, and are involved in the development of skin necrosis and hemolysis [18, 19]. Sphingomyelinases D (SMases D) catalyze the hydrolysis of sphingomyelin, which releases choline and ceramide 1-phosphate. Because SMases D are also able to hydrolyze a broad range of phospholipids, such as lysophosphatidylcholine (which releases lysophosphatidic acid), they are being reconsidered as phospholipases D. *Loxosceles* venom also contains numerous other enzymes including collagenases, alkaline

phosphatases, phosphohydrolases, hyaluronidases, and metalloproteinases. Hyaluronidase might facilitate the gravitational spread of the toxin through the tissue [20, 21].

Electrical stimulation of the cephalothorax of a brown *Loxosceles* spider yields only a few microliters (approximately 4 μ L) of venom. The amount and the content of venom depends on several factors related to the animal, such as size, sex, age, nutritional state, and particular species [12, 13, 16, 17]. Female *Loxosceles* spiders produce larger amounts of venom than do their male counterparts, which could be related to their differences in size and weight. In addition, venom from the females has been shown to induce more intense skin necrosis and hemolysis. Furthermore, the amount and content of *Loxosceles* venom has been found to vary among species. Among rabbits experimentally inoculated with *Loxosceles* venom, skin lesions are larger in those injected with venom from *L. laeta* than in those injected with venom from *L. intermedia*. Venom from *L. laeta* has also been shown to cause more hemolysis in vitro than does *L. intermedia* venom [22, 23].

The best laboratory animal model for the study of venom-induced skin lesions is the rabbit, which develops necrotic skin lesions with a gravitational spreading pattern similar to that observed in human envenomation [12, 23–25]. In envenomed rabbits, histopathological skin changes include endothelial thickening, edema, vasodilatation, vessel wall degeneration, hemorrhage into the dermis, dermal-epidermal dissociation, vacuolization of basal layer keratinocytes, and infiltration by inflammatory cells, especially by polymorphonuclear leukocytes (PMNs), all of which are time dependent. By 3 h after subcutaneous injection of venom, edema and subcutaneous hemorrhage are observed, as is PMN accumulation in and around venules. For more than 48 h, PMNs continue to infiltrate the affected area [12, 26–29]. The PMN infiltrate, in part recruited by indirect activation of the complement system, is considered a major contributor to tissue damage. When neutropenia is induced in rabbits, the development of the characteristic venom-induced lesions is inhibited: Biopsies taken at

3 and 6 h after leukocyte depletion in rabbits show slight edema, absence of PMN infiltration, and no vasodilation or hemorrhage. Similar treatment of guinea pigs to deplete complement also inhibits the formation of venom-induced necrotic lesions: Biopsies taken from injection sites at 3 and 6 h after envenomation show no PMN infiltration. However, although complement depletion prevents the influx of neutrophils in rabbits and neutrophil influx is also reduced in rabbits with genetic C6 deficiency, that does not prevent the hemorrhage and collagen injury [12, 30–32].

Loxosceles SMase D has been shown to induce expression of matrix metalloproteinases (MMPs) in rabbit skin, as well as inducing apoptosis and MMP expression of keratinocytes, which is inhibited by tetracyclines [33]. In addition, in erythrocytes SMase D induces activation of membrane-bound metalloproteinases, resulting in cleavage of glycophorins, which facilitate complement activation via the alternative pathway, resulting in cell lysis. Furthermore, SMase D activates the classical complement pathway in erythrocytes, probably by inducing a loss of membrane asymmetry, leading to exposure of phosphatidyl serine on the external lipid monolayer, which allows the binding of C1q, the first component of the classical complement pathway, followed by activation of that pathway, resulting in hemolysis [34, 35]

Clinical Presentation

In most accidents caused by *Loxosceles* spp., the spider responsible is not captured for identification, often not even having been seen. Therefore, the diagnosis is usually presumptive and can be incorrect. In the absence of a known agent, the diagnosis is based on epidemiological information (the spider is commonly found in the area where the bite occurred, or the circumstances of the accident are consistent with *Loxosceles* behavior) and on the clinical manifestations (skin lesion, systemic response, etc.) On the basis of clinical and epidemiological data, envenomation can be classified as follows [36]:

Putative: spider not known to be in area, atypical skin lesion

Presumptive: spider known to be in area, compatible lesion, typical clinical course

Probable: spiders found in area, patient may have felt bite, seen a spider, typical lesion, typical clinical course

Documented: spider found after bite, identified by qualified person, typical lesion, typical clinical course

Forms

The *Loxosceles* bite can evolve to skin lesions, which can (in rare cases) be accompanied by intravascular hemolysis. The clinical course depends on many variables, such as the amount of venom inoculated; the species, sex, and stage of development of the spider; the anatomical region affected by the bite; and the age, premorbid health status, and immune response characteristics of the patient. Depending on the clinical presentation, loxoscelism is classified as being in one of two forms: cutaneous or cutaneous-hemolytic.

Cutaneous loxoscelism is the more common of the two forms of loxoscelism, occurring in 87.0–99.9% of cases [37]. The victim develops a skin lesion with a relatively slow course that can progress to necrosis. In most cases, there is only one bite site, although there have been a few reports of cases in which there were two or more bites. The bite is mildly painful, reported as a pinprick or itching sensation, and some victims do not feel the bite, because they are bitten in their sleep. Approximately 2–6 h after the bite occurs, the intensity of the pain can increase and can be accompanied by edema and erythema at the bite site. In the first 24 h, a lesion characteristic of cutaneous loxoscelism can evolve, with a painful, irregular macula showing a mixture of violaceous and pale areas (Fig. 4), which is often surrounded by erythema (the hallmark “red, white, and blue sign”) (Fig 5). Serous, serosanguineous, or hemorrhagic vesicles can be seen, as can bullae (Fig. 6). The lesion evolves to induration and, roughly 7–10 days after the spider bite, progresses

Fig. 4 Clinical course of cutaneous loxoscelism: (a) Lesion with ecchymosis and pale, 3 days after the bite. (b) Nineteen days after the bite

Fig. 5 Clinical course of cutaneous loxoscelism: (a) Violaceous lesion with erythematous halo observed around, 3 days after the bite. (b) Twenty days after the bite, patient evolved without necrosis/ulcer

to a dry, necrotic eschar with well-defined edges (Figs. 7 and 8). The necrotic tissue sloughs off in the second or third week, leaving an ulcer of variable depth and extent (Fig. 9). Lesions are typically more severe when the bite affects an area with a higher concentration of fatty tissue, such as the thigh, buttock, or abdomen. In areas such as the face and genitals, an edematous form, characterized by extensive edema and erythema with no progression to necrosis, can occur. When the face or neck is bitten, the edema can be so extensive that respiration is impaired. It is difficult to predict the depth, width, or evolution of skin necrosis. Not all bites evolve to violaceous/pale lesions (Fig. 10), and not all violaceous lesions progress to necrosis [38–43].

The cutaneous-hemolytic form of loxoscelism is also known as systemic or visceral-cutaneous loxoscelism. However, because systemic manifestations are also present in the cutaneous form, the denomination “systemic loxoscelism” is not an appropriate term to describe *Loxosceles* envenomation that progresses to hemolysis. Cutaneous-hemolytic loxoscelism is the most severe form of loxoscelism, characterized by intravascular hemolysis in addition to the skin lesion. It is less common than the cutaneous form and sometimes can be fatal. The frequency of the cutaneous-hemolytic form varies according to the species of *Loxosceles*: in areas endemic for *L. laeta*, the reported frequency of cutaneous-hemolytic loxoscelism 13–16% [38, 40], compared with up to only 10%

Fig. 6 Cutaneous loxoscelism; all cases are probable. (a) Three days after bite. (b): Five days after the bite. (c) Six days after the bite

Fig. 7 Clinical course of cutaneous loxoscelism. (a) Cutaneous necrosis, 7 days after the bite. (b) Necrotic eschar, 19 days after the bite

in areas endemic for *L. gaucho* [43]. The cutaneous-hemolytic form is also rare in areas where *L. reclusa* is the predominant *Loxosceles* species [44], being very rare in areas where *L. intermedia* [45] and *L. rufescens* [46] are more

common. Cutaneous-hemolytic loxoscelism has also been noted with increasing frequency in children [40]. Glucose-6-phosphate dehydrogenase deficiency has been documented in some patients with the hemolytic form of loxoscelism

Fig. 8 Clinical course of cutaneous loxoscelism. (a) Lesion with ecchymosis and areas of pallor, 3 days after the bite. (b) Necrotic eschar, 39 days after the bite

Fig. 10 Skin lesion 1 day after bite by *L. gaucho*. Patients evolved without necrosis

Fig. 11 Cutaneous-hemolytic loxoscelism, 24 h after the bite. (a) Cutaneous lesion. (b) Hemoglobinuria

[47]. Hemolysis can be acute or insidious, occurring between 48 and 96 h after the bite. However, the clinical signs of intravascular hemolysis, such as anemia, jaundice, and hemoglobinuria (Fig. 11), usually occur within the first 24 h after the bite [12]. Subclinical hemolysis has been reported in envenomation occurring in regions where most spider bites are attributed to *L. gaucho* [43]. No correlation exists between the severity of the local injury and severity of hemolysis.

In the cutaneous and cutaneous-hemolytic forms of loxoscelism, nonspecific systemic manifestations have been described, including papular and macular exanthema (Fig. 12), palmar and plantar erythema, pruritus, headache, weakness, malaise, lightheadedness, nausea, vomiting, and fever [12, 43]. Palpable purpura and pustular lesions have also been reported [48–51]. Systemic manifestations are relatively common (Table 1) and are generally noted within the first 48 h after the bite. When present, such manifestations help establish the diagnosis of loxoscelism. Some victims exhibit skin sloughing 2–3 weeks after the bite (Fig. 13).

Complications

Local: Secondary infection is infrequent and is attributable to host flora (streptococci or

Fig. 12 Macular-papular exanthema in patient with loxoscelism probable, 6 day after the bite

staphylococci); when such infection does occur, it does so during the necrotic eschar stage [43].

Systemic: In the cutaneous-hemolytic form, acute kidney injury (AKI) [52] and disseminated intravascular coagulation (DIC) can occur as complications of intravascular hemolysis. Experimental studies have shown structural changes in the kidneys of animals injected with *Loxosceles* venom or toxin [53–55]. However, in a case series of human loxoscelism, AKI and DIC were found to be

infrequent, occurring only when there was massive hemolysis [43].

In the presence of massive hemolysis and AKI lung congestion, there can be electrolyte changes, cardiac arrhythmia, metabolic acidosis, hypoxemia, shock, and bleeding due to DIC.

Histopathological Alterations

Biopsies of skin lesion from patients with loxoscelism show vasodilation, edema, and thickening of the endothelium, together with thrombosis, vascular leakage, and accumulation of PMNs [12, 28]. Some authors have reported that the features most characteristic of loxoscelism are degenerative lesions and coagulation necrosis in sweat glands [56]. In the autopsy of a patient who died 31 h after a bite, most organs showed

Fig. 13 Sloughing of hands and feet observed over the course of loxoscelism

congestive and hemorrhagic phenomena, which were most pronounced in the kidneys [28]. A biopsy of an exanthematous lesion revealed necrotizing vasculitis without epidermal necrosis [49].

Laboratory Tests

There is no routine test to obtain a definitive diagnosis of *Loxosceles* envenomation. Although an enzyme-linked immunosorbent assay to detect the venom in samples collected from patient lesions (hair, aspirate, swab, or biopsy specimens) and a test to determine the circulating levels of antibodies to the venom have been studied, such tests have not been validated for clinical use [57–60]. However, certain alterations can be found in the laboratory test results of envenomed individuals with the cutaneous or cutaneous-hemolytic forms of loxoscelism [43]:

Hemoglobin: low in massive hemolysis

Leukocytes: leukocytosis and absolute or relative neutrophilia found in both forms

Platelets: normal in most cases; thrombocytopenia in some cases of the cutaneous-hemolytic form

Reticulocytes: elevated in the cutaneous-hemolytic form, especially in the second week after envenomation

Bilirubin and lactate dehydrogenase: bilirubin (total and indirect) and lactate dehydrogenase both elevated in the cutaneous-hemolytic form

Urea, creatinine, sodium, and potassium: normal values in most cases; abnormal values in cases of hemolysis with AKI

Alanine aminotransferase, aspartate aminotransferase, and creatine kinase: occasionally elevated in both forms; higher in cases of the cutaneous-hemolytic form

C-reactive protein: elevated in both forms; higher in cases involving hemolysis – even subclinical hemolysis

Fibrinogen: elevated in both forms; however, low fibrinogen level is found if there is DIC

Prothrombin time and activated partial thromboplastin time: normal in most cases; altered in cases involving massive hemolysis and DIC

D-dimer: potentially elevated in both forms

Blood gases: metabolic acidosis may be seen in massive hemolysis and AKI

Haptoglobin: low in massive hemolysis

Direct antiglobulin test: positive in some cases of the cutaneous-hemolytic form [61]

Urine: hemoglobinuria; hematuria in the cutaneous-hemolytic form

Differential Diagnosis

Over the decades, many spiders have been implicated as necrotic agents but subsequent rigorous evidence-based research has shown that many of these spiders were wrongly accused. Depending on the stage of the lesion, other causes of skin lesions are included in the differential diagnosis of cutaneous loxoscelism: insect bite, allergic dermatitis, infections (cellulitis, cutaneous abscess, necrotizing fasciitis, cutaneous leishmaniasis, and fungal infection), pyoderma gangrenosum, lymphomatoid papulosis, chemical burn, frost-bite, focal vasculitis, ischemic vascular disorders, factitious ulcers, and traumatic lesions [37, 62]. In patients with hemolysis, the diagnosis of loxoscelism is strengthened by the presence of a skin lesion with a typical clinical course.

Treatment

In cases of *Loxosceles* envenomation, the goals of treatment are to manage the skin lesion and prevent or minimize the hemolysis, as well as to provide symptomatic therapy, supportive therapy for complications, and wound care (when necrosis has already occurred). There is no consensus regarding the best treatment for loxoscelism, and the standard treatment varies among the regions of the world where *Loxosceles* bites occur. Treatments

prescribed for loxoscelism include antivenom, corticosteroids, dapsone, antihistamines, antibiotics, hyperbaric oxygen, electric shock, surgical excision, and vacuum-assisted wound closure [15, 63]. However, due to the lack of clinical trials, there is little evidence to indicate that any of those methods is superior to the others. In addition, the *Loxosceles* antivenom is available only in certain countries in South America. Tetanus prophylaxis is recommended for all *Loxosceles* bite victims.

Skin Lesion and Hemolysis

Antivenom

Antivenom has been used to reduce the size of the cutaneous lesion as well as to treat the hemolysis that occurs in the cutaneous-hemolytic form. However, there have been no clinical studies providing evidence of the effectiveness of antivenom in loxoscelism or regarding the timing of its use. Nevertheless, a controlled experimental study using *L. intermedia* venom in rabbits showed that the necrotic injury was approximately 90% smaller when the antivenom was administered within the first 6 h after venom injection. Even when the antivenom was administered as late as 48 h after venom injection, the lesion was approximately 30% smaller than the control lesion [25]. *Loxosceles* antivenoms are available in Brazil, Argentina, Peru, and Mexico. All except one (a whole IgG antivenom from Peru) are horse-derived F(ab')₂ antivenoms. The indications for antivenom therapy depend on the time of progression, the characteristics of the cutaneous lesion, and the clinical presentation. Unfortunately, delayed diagnosis of loxoscelism frequently restricts the use of the antivenom for preventing the necrotic lesion. The Ministries of Health of Brazil, Peru, and Argentina recommend the use of intravenous antivenom in cases of cutaneous or cutaneous-hemolytic loxoscelism [45, 64, 65]. In Brazil, antivenom administration is recommended in cutaneous-hemolytic loxoscelism patients who present with hemolysis, even if treatment is not given until 48 h after the bite.

Corticosteroids

Among clinical and experimental studies, there is no consensus on the efficacy of corticosteroids in the treatment of cases of cutaneous lesion or hemolysis caused by loxoscelism, and there have been no clinical trials evaluating their use in such cases. However, corticosteroids have been prescribed for the cutaneous-hemolytic form in Chile and in the United States [36, 41, 66, 67]. Short courses of systemic corticosteroids (5–7 days) are widely used for the treatment of loxoscelism in Brazil – with or without the antivenom in cases of cutaneous loxoscelism and with the antivenom in cases of the cutaneous-hemolytic form. For the cutaneous form, prednisone (40–60 mg/day) has been used. In cutaneous-hemolytic loxoscelism, corticosteroids have been administered intravenously (at doses equivalent to 1 mg/kg/day of prednisone) for 5–10 days [45]. It has also been recommended that adults and children with cutaneous-hemolytic loxoscelism receive intravenous methylprednisolone (or the equivalent) at a loading dose (based on ideal body weight) of 1.0–2.0 mg/kg, followed by doses of 0.5–1.0 mg/kg every 6 h, for 5–10 days [62]. Intralesional injection of corticosteroids is not recommended, because it could exacerbate the edema and pressure at the injection site, thus promoting necrosis [12].

PMN Inhibitors

Among the drugs that act on PMNs, dapsone is the most widely used, especially in the United States. Although experimental studies in envenomed guinea pigs showed that dapsone reduces the extent of cutaneous lesions [68], similar studies using a rabbit model found that the use of dapsone provided no benefit compared with the control condition [69, 70]. In addition, there have been no clinical studies showing that dapsone is an efficacious therapy for the cutaneous form of human loxoscelism. Furthermore, at therapeutic or supratherapeutic doses, dapsone is associated with hemolytic anemia and methemoglobinemia, especially in

children [71]. The adult dose of dapsone is 25–100 mg orally, twice daily.

Metalloproteinase Inhibitors

In addition to their antimicrobial effects, drugs such as tetracyclines and chemically modified tetracyclines have anti-inflammatory and immunomodulatory properties, including the ability to inhibit metalloproteinases. Tetracycline derivatives inhibit both the activity and production of MMPs. One experimental study demonstrated that the topical tetracycline, initiated 6 h after injection of venom or toxin with SMase D activity and administered twice daily thereafter, prevented necrotic skin lesions. However, there have been no clinical studies evaluating this form of treatment [72].

Other Treatment Modalities

Hyperbaric oxygen has been proposed as a means of preventing necrosis in loxoscelism. The results of experimental studies are inconclusive as to the effects of this treatment modality on the skin lesion [69, 73–75]. Although the findings of one uncontrolled clinical study indicated lesion improvement after hyperbaric oxygen use, the treatment has also been reported to worsen the lesion [76]. There have been no studies evaluating the effect that hyperbaric oxygen has on the healing of existing lesions caused by loxoscelism.

Topical nitroglycerin ointment was studied in rabbits experimentally injected with *L. reclusa* venom. The results show that this treatment modality is potentially harmful, increasing edema, inflammation, and creatine kinase concentrations [77].

It has been suggested that nonpharmacological therapies, such as electric shock and negative pressure, can prevent the necrotic lesion when used as the initial treatment for loxoscelism. The use of electric shock, based on previous experiences with snakebites, has been assessed in guinea pigs [68]. However, no beneficial effect of electric shock was observed in animals receiving the treatment 16 h after venom injection. An experimental study showed that negative pressure therapy, initiated early, improved the healing of cutaneous

lesions induced by the injection of *Loxosceles* venom in pigs [78]. However, additional experimental studies are needed in order to justify clinical studies of these types of nonpharmacological therapies.

Symptomatic Therapy

Analgesics

After a *Loxosceles* bite, analgesics are required, especially in the first week, when the pain is more intense. In general, either paracetamol or dipyrone is sufficient for pain control. However, opioids are required in some cases.

Antihistamines

There is no evidence that antihistamines influence the clinical course of the cutaneous injury in loxoscelism [70]. However, their administration is indicated in patients who develop pruritic exanthema.

Care of the Cutaneous Lesion (Eschar/Ulcer)

Antibiotics

In the United States, antibiotics have been administered as part of the initial treatment of the skin lesion resulting from a *Loxosceles* bite [36, 41, 44, 79]. However, infection is uncommon and, when present, occurs in the eschar stage, usually more than 2 weeks after the bite. Therefore, antimicrobial prophylaxis is not indicated and treatment should only be conducted with evidence of secondary infection. The selected antimicrobial spectrum should cover the skin flora.

Surgical Management

Early surgical intervention is not indicated for a skin lesion resulting from a *Loxosceles* bite, because surgery can amplify the inflammation and exacerbate the effects of the venom, thus protracting tissue injury and increasing lesion size, as well as worsening functional and cosmetic

outcomes [37]. The necrotic tissue should be approached only after its limits are well defined, which typically occurs more than 2 weeks after the bite. Following the debridement of the necrotic eschar, an ulcer containing fibrin and devitalized fatty tissue is often observed, in which case chemical debridement is indicated. Most victims of a *Loxosceles* bite present with small, superficial necrotic lesions that will heal completely with basic care. If major tissue loss ensues, the need for skin grafting will have to be evaluated.

Supportive Therapy for Hemolysis

Hydration

Victims of a *Loxosceles* bite should receive adequate hydration with crystalloid solution, in order to maintain a urine output of 1–2 mL/kg/h for children and 30–40 mL/h for adults. Adequate renal perfusion and increased urine flow are important measures to prevent AKI-induced pigment. Care should be taken to avoid volume overload, especially in children, in individuals with heart disease, and in individuals with anuria.

Renal Replacement Therapy

In loxoscelism patients with AKI, the need for renal replacement therapy should be assessed. Renal replacement therapy is usually indicated in patients with fluid overload that does not respond to diuretics, as well as in those with anuria, electrolyte disturbances, acid–base disorders, or uremia.

Packed Red Blood Cell Transfusion

Loxoscelism patients with severe anemia should receive packed red blood cell transfusion. In such patients, DIC is uncommon and there is rarely a need for transfusion of fresh frozen plasma or platelets.

Plasma Exchange

In patients with cutaneous-hemolytic loxoscelism plasma exchange is reported for management in case of refractory hemolysis [80–82].

Widow spiders (Family Theridiidae; genus *Latrodectus*) are found throughout the world. Bites from these spiders may cause a neuroexcitatory envenoming with intense muscle spasm and autonomic dysfunction. This clinical syndrome, called *latrodectism*, is seldom fatal but may present a diagnostic dilemma and cause significant morbidity.

It is difficult to estimate the annual number of patients who experience clinically significant envenomation. Currently in the United States, approximately 2500 cases are reported to poison centers each year. Of these, approximately 900 require treatment in a health care facility [1–3]. Mortality is rare, but a number of deaths have been reported, particularly in the past and especially in the pre-antivenom era. In North America, data from 1950–1959 indicated 63 deaths ascribed to widow spider bite (at that time all would have been considered *L. mactans*) with highest numbers in some southern and eastern states, but little data on cause of death [4]. In this study, 31% of deaths were in children under 10 years of age and only 32% of deaths occurred in the first 24 h, which may indicate causes of fatality other than direct venom effects in at least some cases [4, 5]. In Australia, there are at least 13 reported fatalities associated with *Latrodectus* bites, all in the pre-antivenom era prior to 1956 [6]. In greater Europe at least some fatal bites have been reported historically and also numerous documented episodes of epidemic latrodectism dating back over a thousand years, notably in

countries bordering the Mediterranean Sea and in Russia [5, 7]. In recent times there are two reported deaths associated with *L. geometricus* in Madagascar and one from a bite by *L. tredecimguttatus* in Greece [8, 9]. No verified cases of death due to latrodectus envenomation have been recorded in the USA in recent decades, and no deaths have been reported in Australia for 60 years. These figures exclude the exceptionally rare fatality associated with the use of antivenom to treat latrodectism. Australia may have the highest rate of latrodectism in the world. An estimated 5000–10,000 latrodectus bites to humans occur annually in Australia, but only 20% require antivenom therapy and no antivenom-related fatalities have been reported [10].

Widow spiders are present on all continents except Antarctica. Clinically significant spiders include *Latrodectus mactans*, *Latrodectus hesperus*, *Latrodectus bishopi*, *Latrodectus geometricus*, and *Latrodectus variolus* in North America; *Latrodectus hasseltii* (redback spider) in Australia; *Latrodectus katipo* in New Zealand; and *Latrodectus indistinctus* in South Africa. *Latrodectus geometricus* (brown widow) and *Latrodectus tredecimguttatus* are found on most continents. The Australian species, Australian species, *L. hasseltii*, has successfully colonized other regions including New Zealand, Japan, and parts of the Arabian Peninsula. These spiders appear to be environmentally adaptable and well able to spread through human activities. The taxonomy of the genus was the subject of debate throughout the twentieth century. Between five and forty species have been described with many allopatric (speciation that occurs when a population becomes segregated into two populations by a geographic barrier) populations being described by trinomials (e.g., *L. mactans hasseltii*) [5, 11].

Widow spiders are small with a protuberant abdominal section. Many species have specific but variable ventral or dorsal abdominal markings. The red hourglass marking is only present in the female of some species such as *L. mactans* and *L. hasseltii*. Male widow spiders are smaller

than females, reach maturity earlier than females, live only 1 or 2 months, and die soon after mating. Males have a small biting apparatus and generally are considered to be unable to envenom humans, though rare instances of mild envenomation have been claimed [12]. Female widow spiders are much larger, live several months, and are able to envenom humans. There is no scientific evidence to confirm the popular conception that the female spider routinely eats her mate. The term *widow* probably arose from the observations that males seldom are seen in the web. Widow spiders produce an irregular, untidy web to catch their prey, usually in a position where they can establish sticky drop lines to a flat surface with the spider residing high in the web. They are not aggressive and bite humans only when trapped against the skin. They often live in environments where they readily come into contact with humans. *Latrodectus* spp. bites to humans tend to occur in warmer months or just when the weather turns cool and the spiders migrate indoors [13].

Hundreds of therapies have been offered for patients envenomed by widow spiders, including warm baths, alcoholic beverages, opioids, various sedative-hypnotic agents, neostigmine, physostigmine, atropine, tubocurarine, methocarbamol, dantrolene, procaine, corticosteroids, magnesium, calcium, and antivenom, to name just a few [5, 7, 14, 15]. Therapies that are truly efficacious are described in the treatment section.

Biochemistry

Latrodectus venom contains a family of high-molecular-weight proteins that lead to transmitter release from nerve endings [16]. One study that compared the venoms of four black widow species (*L. mactans*, *L. variolus*, *L. bishopi*, and *L. geometricus*) showed that the electrophoretic patterns of all the venoms were similar, and one antivenom prevented the lethal effects of all venoms in a mouse model [17]. More recently,

the venom of *L. tredecimguttatus* has been studied in depth [16]. All *Latrodectus* species seem to produce α -latrotoxin, with a molecular weight of approximately 150,000 kDa [17–19].

Pathophysiology

It is thought that α -latrotoxin leads to the clinical envenomation syndrome in humans, whereas the latroinsectotoxins lead to venom toxicity in invertebrates. In vertebrates, the existence of calcium-dependent and calcium-independent binding proteins on the presynaptic membrane has been demonstrated [16]. Binding of α -latrotoxin to one or more of these proteins, notably latrophilin 1 or neurexin 1 α , facilitates the insertion of the α -latrotoxin tetramer into the membrane, with the formation of a central Ca^{++} permeable transmembrane pore, leading to presynaptic transmembrane influx of calcium or other ions [20]. This leads to vacuole release of neurotransmitters such as acetylcholine, dopamine, norepinephrine, glutamate, and gamma-aminobutyric acid, depending on the type of synaptic cleft involved. Uncontrolled release of neurotransmitters such as acetylcholine in the brainstem, spinal cord, and neuromuscular junction and possibly release of catecholamines in the brain, spinal cord, or autonomic ganglia, result in norepinephrine discharge and lead to the clinical manifestations of envenomation. The degree to which the various neurotransmitters are released in humans is uncertain and must be inferred from in vitro studies [18]. In addition it appears some actions of α -latrotoxin on vesicle exocytosis involve receptor binding and subsequent stimulation of intracellular signaling with Ca^{++} release [20].

Clinical Presentation

The clinical syndrome of latrodectism varies slightly depending on the species involved and the amount of venom injected [5, 7]. *L. mactans* is notorious for causing abdominal rigidity and

Fig. 1 Target lesion after the bite of a *Latrodectus* spider

back pain, whereas *L. hasseltii* seems to cause more diaphoresis. *L. geometricus* tends to cause local symptoms [21]. Mortality is currently rare and was never common, even in the pre-antivenom era, though myocarditis resulting in death has been reported with *L. tredecimguttatus* envenomation in Greece [9]. Two deaths have been reported in Madagascar where two species are known, *L. geometricus* and *L. menavodi*; in one case there was cardiovascular failure and in the other foot gangrene, though the latter is not readily explainable as a consequence of latrodectism, and the identity of the spider may be uncertain [8]. A number of other causes of death have been reported including pulmonary edema, a more likely sequelae of severe neuroexcitatory envenoming [5, 7].

The bite itself is often only minimally painful and may go unnoticed as some patients may not have progressive symptoms. Local pain becomes apparent within 10–60 min in most cases, though can be delayed in onset by many hours, and discomfort may spread to regional lymph nodes and beyond. A triad of local pain, diaphoresis, and piloerection may occur in addition to the presence of mild erythema around a central pale area, giving rise to the term *target lesion* (Fig. 1), though this is not a universal feature [5, 7]. In at least some series three quarters of patients develop only self-limiting local effects and do not subsequently develop systemic effects [13].

Systemic envenomation may take many hours to reach its full extent. Muscle pain occurs around the bitten area and then becomes generalized.

Patients may describe neck, chest, abdominal, lower back, and thigh pain. This pain often is associated with generalized diaphoresis and dysphoria. Associated features include low-grade fever, tachycardia, hypertension, tremor, paresthesias, headache, and occasionally vomiting. The use of a visual analog scale as well as a clinical grading system has been proposed to classify severity of envenomation [15, 22], based on the presence or absence of local and generalized signs and symptoms, but it has not been validated as a method to predict outcome or complications.

The term *facies latroductismica* describes the contorted grimace, general flushing, diaphoresis, trismus, and blepharoconjunctivitis sometimes seen in patients with full-blown latroductism [5, 7, 14]. Compartment syndrome, rhabdomyolysis, myocarditis, troponin elevation, and priapism have also been reported [8, 9, 23–26]. Altered mental status has been described, particularly in elderly patients. It is unclear whether this altered mental status is true delirium or a state of severe dysphoria. Generalized muscle weakness has been described up to 96 h after envenomation [27]. Chronic pain syndromes lasting weeks to months have been described [28]. In these cases, late antivenom therapy has been associated with resolution of symptoms. Whether this is a placebo effect or an actual action of the antivenom is unknown. Rare reported complications associated with latroductism include herpes zoster [29], priapism [24, 25, 30], and toxic epidermal necrolysis [31]. The degree to which these complications truly are related to latroductism is unknown because these are uncontrolled observations. However, priapism is a well-described feature of envenoming by the banana spider in Brazil, *Phoneutria nigriventer*, which has a broadly similar form of neuroexcitatory envenoming and clinical effects, and so is likely to be a true effect of latroductism envenomation [5].

Diagnosis

The diagnosis of latroductism is clinical and there are no specific confirmatory laboratory tests. The decision to order laboratory tests should be

dictated by the clinical situation for evaluation of sequelae resulting from envenomation. Case reports have described latroductism being mistaken for an acute abdomen with subsequent negative laparotomy, acute myocardial infarction, meningitis, psychosis, renal and biliary colic, peritonitis, malaria, porphyria, lead intoxication, and sickle cell crisis [5, 14].

Treatment

Treatment should initially focus on airway management and respiratory and circulation support as needed. Tetanus prophylaxis and wound care should also be addressed.

Treatment modalities advocated for latroductism have included opiates, benzodiazepines, muscle relaxants, calcium, and antivenom [5, 14]. Few studies have examined the efficacy of these treatments. The consensus among clinical toxicologists is that first-line treatment of patients with moderate latroductism in North America should be directed toward pain management with a combination of an opioid and a benzodiazepine, although this has not been studied prospectively (Grade II-2 recommendation). Severe systemic manifestations (e.g., severe muscle pain, diaphoresis, dysphoria, hypertension, prenatal labor) refractory to a combination of opioids and benzodiazepines in generous doses should prompt strong consideration of antivenom therapy (Grade II-2 recommendation). In Australia, a far lower threshold for its use has been accepted [5, 12]. It commonly has been given for regional or systemic envenoming, without first using an opioid and a benzodiazepine. One group of toxicologists have recently advocated a different view in Australia, with their research indicating the antivenom is ineffective and they no longer recommend its use [32]. However, this view is contested by others who point to significant problems with the study on which these recommendations were based [33–35]. Further, this study, while being interpreted as showing antivenom was ineffective, also demonstrated that analgesia failed to provide adequate symptom control in 75% of cases [32]. Thus in Australia, at the time of this writing,

there are two distinct and mutually exclusive views of best practice treatment of latrodectism.

Indications for ICU Admission in Envenomation by Widow and Related *Latrodectus* Spiders

- Requirement for continuous high-dose infusion of opioids and benzodiazepines in patients in whom antivenom is contraindicated
- Rare complications, such as electrocardiogram changes, acute myocardial infarction, or pulmonary edema
- Clinical monitoring during antivenom infusion (short-term admission) if safe monitoring cannot be achieved outside this setting
- Anaphylactic or severe anaphylactoid reactions complicating antivenom infusion

Though calcium was considered an important treatment modality for much of the twentieth century, one retrospective review of 163 patients concluded that calcium gluconate was ineffective for relief of pain when compared to IV benzodiazepines and opioids. Of the 24 patients with severe envenomation who initially received calcium gluconate, 23 reported no relief of symptoms [15]. Calcium should, therefore, no longer be considered to have antidotal properties for the treatment of latrodectism.

Dantrolene and methocarbamol have not been proven to be effective treatment modalities [36, 37]. Treatment of envenomation by *L. mactans* with intravenous calcium gluconate and methocarbamol was compared in a small ($n = 13$) prospective crossover study [36]. All four patients treated initially with methocarbamol required further treatment. In the series by Clark and colleagues [15] of 163 patients, 75 patients with severe envenomation received parenteral opioids. In this group, 55% of patients treated with opioids alone obtained symptomatic relief, whereas 70% of patients treated with combined opioids and benzodiazepines obtained symptomatic relief after initial treatment. It was concluded that benzodiazepines conferred an opioid-sparing effect when given with morphine. Antivenom was administered to 58 patients in Clark's series, one

of whom died, apparently to a hypersensitivity to antivenom. This patient had a history of atopy and asthma and the antivenom was administered as a bolus. Antivenom led to complete resolution of symptoms within 2 h (mean time 31 ± 26.7 min), and relapses did not occur, although seven patients (12%) required two doses. Patients who received antivenom had a shorter duration of symptoms (9 ± 22.7 h compared with 22 ± 24.9 h, $P < 0.05$) and were less likely to be admitted to the hospital (12% compared with 52%). Hypertension rarely required specific treatment, usually responding to supportive care or antivenom. Minor urticarial reactions occurred in four (7%) patients who received antivenom. Only nine of the 58 patients treated with antivenom were followed up by telephone at a later date; however, none of these patients reported symptoms suggesting delayed hypersensitivity reactions.

Antivenom Therapy

North America

The North American black widow antivenom is an equine IgG-rich preparation. The equine serum is pooled and partially purified to produce the lyophilized antivenom. Traditionally, the initial dose for adults and children is one vial (2.5 mL) diluted in 50 mL of saline. The generally accepted indication for antivenom is severe systemic effects (e.g., muscle pain, diaphoresis, dysphoria, hypertension) refractory to a combination of opioids and benzodiazepines and high-risk situations such as pregnancy (Grade II-2 recommendation). Based on our current state of knowledge, children, elderly patients, and pregnant patients are treated according to the same indications. Antivenom should be considered contraindicated in patients with known hypersensitivity to equine serum. Caution is indicated in patients with a history of severe asthma and atopy (Grade III recommendation). The two deaths that have been reported to date after intravenous administration of the antivenom occurred in patients with a history of asthma [15, 38]. The exact incidence of immediate hypersensitivity reactions is unknown.

Delayed type III hypersensitivity (serum sickness) may occur. The exact incidence is unknown.

If antivenom is considered, we recommend that:

1. The risks and benefits of this treatment be discussed with the patient.
2. The patient be placed in a clinical setting where acute allergic reactions can be managed.
3. Reliable intravenous access be achieved, and electrocardiographic and pulse oximetry monitoring be started.
4. The immediate bedside availability of invasive airway equipment, epinephrine and antihistamines be ensured.

There is no good evidence that skin testing reliably predicts reactions to antivenom; therefore, we do not support skin testing on medical grounds as positive and negative predictive values are poor [39].

The product information from Merck (West Point, PA), the manufacturer of the antivenom, recommends that it be given intramuscularly, unless it is administered to a critically ill adult or a child younger than 6 years old, in which case the intravenous route is recommended. However, the usual practice by medical toxicologists for many years has been to deliver the antivenom routinely to all patients by the intravenous route. This practice may relate to the hypothesis that the intravenous route is safer because the dose may be truncated if hypersensitivity signs or symptoms occur [40]. Premedication with subcutaneous epinephrine, antihistamines, or corticosteroids is controversial. It has not been part of routine practice for this antivenom in the United States. There is evidence that premedication with low-dose subcutaneous epinephrine reduces the incidence of acute allergic responses associated with the intravenous infusion of certain snake antivenoms with a high incidence of major adverse reactions [41], but premedication has not been studied in *Latrodectus* antivenom administration.

If the intravenous route is chosen, the most recent package insert recommends an initial dose

of 2.5 mL (one vial) diluted in 10–50 mL of saline administered over 15 min [42]. Despite the recommendations in the package insert, many toxicologists have advocated administration in greater volumes of fluid over a longer period of time as it is impossible to predict which patients will develop allergic reactions [43]. We recommend that the antivenom be diluted in 50–250 mL of normal saline and the infusion started slowly (e.g., 10 drops per minute). Provided that no allergic symptoms occur, we recommend that the infusion rate can be doubled every few minutes so that the total volume is administered over 60 min. The patient should be observed closely throughout the infusion and for 30 min thereafter. Acute allergic reactions are unlikely to occur more than 30 min after cessation of the infusion, and patients may be discharged as soon as they are clinically well. Routine admission to the intensive care unit of patients with uncomplicated antivenom-treated latrodectism, even if severe, may not be required.

Patients who receive the antivenom by the intramuscular route should be observed to exclude acute allergic reactions and to ensure clinical improvement. Although not formally studied, in our experience, 2 h of observation for allergic reaction is sufficient.

Analatro[®] is a purified F(ab)₂ *Latrodectus mactans* antivenom currently in clinical trials in the United States. It is expected to have fewer adverse reactions than the whole IgG product. It has been available in Mexico since 1998 and marketed under the name Aracmyn[®]. No serious adverse events were reported in a randomized double-blind, placebo-controlled trial of the highly purified equine F(ab)₂ antivenom though the data for safety is limited by the sample size of 24 subjects [44]. A subsequent larger Phase III randomized, double-blind, placebo-controlled trial of this antivenom has initially been reported as showing clear benefit of antivenom versus placebo, with no serious adverse events reported, and the rate of adverse events was similar in both study arms (antivenom and placebo) [35]. The researchers concluded that this antivenom was “effective in reducing moderate to severe pain caused by latrodectism” [35].

Australia

In Australia, redback spider (*L. hasseltii*) bite leads to signs and symptoms similar to those encountered in other parts of the world, including pronounced diaphoresis, tachycardia, hypertension, muscle cramps, tremor, but vomiting is uncommon. The Australian antivenom also is a purified equine-derived IgG-F(ab)₂ product that historically was usually given intramuscularly, though in the last 10–15 years it has commonly been given intravenously [12]. No deaths due to anaphylaxis have been associated with the use of *L. hasseltii* antivenom. In a series of 2144 patients treated over 13 years, the incidence of allergic responses was 0.5%, and there were no deaths [45]. Reactions are usually mild consisting of mainly urticarial and cutaneous manifestations. Incidence of serum sickness is less than 5%. All severe acute allergic responses in this series occurred in patients who received antivenom by the intravenous route, contrary to product recommendations. However, the efficacy of intramuscular administration has recently been questioned [32, 46, 47]. One prospective cohort study found that only 17% of patients treated with intramuscular antivenom had no pain at 24 h [48]. Another randomized controlled trial of intramuscular versus intravenous antivenom found no significant difference between the two routes of administration [46]. Further studies are needed to determine the appropriate use of antivenom and most efficacious route of administration. With the caveat noted earlier of controversy about best practice management of latrodectism in Australia, current Australian practice is to use antivenom for patients with severe local symptoms unresponsive to oral analgesics and in patients with signs or symptoms of systemic envenomation [12]. Benzodiazepines are used only in the rare situations when they are necessary while waiting for the antivenom to work. Most patients (66–97%) treated with antivenom require two vials given by intravenous infusion or intramuscular injection [13, 45, 49]. The remaining patients require additional doses [28].

Skin testing is not recommended in Australia [11, 12], and premedication is controversial [5, 12, 49]. Given the low risk of acute allergic reactions, it would seem reasonable to withhold

premedication, unless the patient has been sensitized to horse serum or has a history of atopy (Grade III recommendation). We recommend that patients should have reliable intravenous access and be placed in an environment where acute allergic reactions can be treated. If repeat doses are required, some authorities recommend the intravenous route using a technique similar to that described earlier for the North American product [12]. We recommend that patients who receive the antivenom by the intramuscular route be observed for 2 h to exclude acute allergic reactions and to ensure clinical improvement before discharge.

L. hasseltii antivenom has been administered by some unorthodox routes. Case reports have described local subcutaneous injection of antivenom to control severe prolonged local symptoms [50] and use of antivenom by a regional intravenous technique similar to the Bier block [51]. These kinds of approaches have not been validated and cannot be recommended.

The exact incidence of delayed-type hypersensitivity (serum sickness) associated with *L. hasseltii* antivenom is unknown, but it is thought to be low. Prophylactic steroid therapy is prescribed by some clinicians in an attempt to prevent serum sickness if multiple doses of antivenom are used [5]. This practice has not been validated experimentally.

New Zealand

The New Zealand katipo spider is similar to the Australian redback spider and should be treated as such [52].

South Africa

Three members of the genus *Latrodectus* are present in South Africa. *L. indistinctus* (black widow) and *L. geometricus* (brown widow) are thought to be chiefly responsible for human envenomation. All of these spiders have venom that contains α -latrotoxin. The relative toxicity of *L. indistinctus* and *L. geometricus* venoms has been studied using a mouse lethality model [53]. The venom of *L. indistinctus* (black widow) seems to be three to four times more potent than that of *L. geometricus* (brown widow). In a retrospective

series of 45 cases [21], *L. indistinctus* (black widow) caused more severe envenomation with systemic signs and symptoms. The presentations of brown widow bites were mild, and local symptoms predominated.

In South Africa, antivenom is administered in severe cases to prevent a protracted course [21]. The equine-derived F (ab)₂ antivenom is given as an intramuscular injection of 5 mL.

Reactions to Antivenom

As stated earlier, allergic reactions to antivenom are uncommon. During intravenous infusion of antivenom, mild isolated urticaria may be treated by slowing the rate of infusion and administering an intravenous antihistamine, such as diphenhydramine. In the setting of latrodoctism, clearly airway swelling, bronchospasm, or hypotension should prompt immediate abandonment of antivenom therapy and aggressive therapy.

The immediate priority of management is the assessment and management of threats to the airway, breathing, and circulation. Intubation and ventilation may be required. First-line therapy consists of oxygen, epinephrine, and intravenous fluids [54]. High-flow oxygen should be given to ensure adequate oxygen saturation. Epinephrine should be administered in all cases with hypotension, airway swelling, or bronchospasm [55] (Grade II-3 recommendation). Large volumes of crystalloid or colloid may be required to maintain circulatory volume and adequate blood pressure.

When the immediate threats to the airway, breathing, and circulation have been managed with airway control and first-line drugs, the use of second-line drugs, such as corticosteroids, antihistamine (H₁ and H₂) blockers, glucagon, and aminophylline, may be considered. Antihistamines should be used in combination with H₂ blockers, such as cimetidine or ranitidine [55, 56] (Grade I recommendation). Corticosteroids are indicated to prevent prolonged sign or symptom duration, especially bronchospasm [57] (Grade II-3 recommendation). Based on theoretical considerations and two case reports, glucagon has been advocated for patients taking

Table 1 First-line therapy for anaphylaxis

Treatment	Dosage
Oxygen	Apply high FiO ₂ oxygen via endotracheal tube or facemask to maintain oxygen saturation >92%
Epinephrine	<i>Early or mild anaphylaxis</i> – 0.3–0.5 mg (0.3–0.5 mL) 1:1000 epinephrine by intramuscular injection repeated every 5–10 min as required <i>Hypotension, dyspnea, airway compromise, or patient deteriorating</i> – 1:100,000 epinephrine 1–2 mL/min IV, repeated as necessary. 1:100,000 epinephrine may be prepared by drawing 1 mg of epinephrine (1 mL of 1:1000) in a 20-mL syringe and adding 9 mL of normal saline to make a volume of 10 mL. All but 2 mL is discarded (leaving 200 µg) before a further 18 mL of saline is added to make 20 mL (10 µg/mL)
Fluid	Give 10–20 mL/kg of crystalloid or colloid for hypotension

FiO₂ fraction of inspired oxygen Adapted from Brown [54], p. 640

β-adrenergic blocking drugs who have an increased risk of anaphylaxis and are resistant to treatment [54, 57] (Grade III recommendation). Aminophylline may be appropriate for patients with bronchospasm resistant to epinephrine and steroids [54] (Grade II-3 recommendation). Tables 1 and 2 provide suggested treatment doses.

Criteria for ICU Discharge in Envenomation by Widow and Related *Latrodectus* Spiders

1. For patients who have not received antivenom, high-dose opioid and benzodiazepine infusions should be ceased. Patients who feel clinically well and have normal vital signs 4 h after starting oral analgesia may be discharged.
2. After intravenous infusion of antivenom, patients may be discharged at the end of the infusion if there is a satisfactory clinical response (patient feels well) and there is no evidence of anaphylactic or anaphylactoid reaction.

(continued)

3. After intramuscular injection of antivenom, patients may be discharged 2 h after injection if there is a satisfactory clinical response (patient feels well) and there is no evidence of anaphylactic or anaphylactoid reaction.

Key Points in the Treatment of Envenomation by Widow and Related *Latrodectus* Spiders

1. Latrodectism is painful and associated with significant dysphoria. Initial doses of opioid and benzodiazepine should be generous and repeated as frequently as necessary.
2. Failure of opioids and benzodiazepines to control symptoms should prompt consideration of antivenom use. Antivenom may be given sooner if it is clear that high doses of opioids and benzodiazepines do not afford clinical relief.
3. Despite the small but finite risks associated with antivenom, prudent use in carefully selected patients is sound clinical practice. Known equine allergy or previous exposure to horse serum should be addressed. Use caution in patients with asthma and history of atopy.
4. Acute allergic responses occur at the time of antivenom administration. Prolonged inpatient monitoring for late reactions is not indicated.
5. Failure of antivenom to alleviate symptoms should prompt administration of an additional dose or may bring the diagnosis into question.

Table 2 Second-line therapy for anaphylaxis

Treatment	Dosage
Antihistamines	Diphenhydramine, 25–50 mg IV, or promethazine, 12.5–25 mg IV, <i>plus</i> cimetidine, 300 mg IV, or ranitidine, 50 mg IV, repeated every 6 h as required. Oral therapy may be started when able
Corticosteroids	Hydrocortisone, 5 mg/kg (≤ 200 mg) IV, followed by 2.5 mg/kg IV every 6 h, or methylprednisolone, 125 mg IV every 6 h. Oral prednisone, 40–50 mg daily, may be started when able
Glucagon	<i>For patients on β-adrenergic blockers</i> – 1 mg IV every 5 min until stable, then 5–15 μ g/min as an infusion
Aminophylline	<i>For refractory bronchospasm</i> – 5 mg/kg IV infused over 30 min followed by an infusion of 0.5 mg/kg/h

Adapted from Brown [54], p. 640

patients that have been treated with antivenom [24, 25]. Detailed physical examination may reveal evidence of a widow bite (e.g., localized diaphoresis, target lesion) (see Fig. 1), or a spider may be found in bedding, in clothing, or beneath the bed. Infants and children have been said to be at increased risk of severe morbidity from latrodectism, but there is little literature, confined to case reports, that specifically addresses the pediatric population.

Pregnant Patients

The effect of latrodectism on pregnancy is not clear. Pregnancy has been cited as an indication for antivenom therapy in case vigorous abdominal muscular contractions lead to fetal distress [58]. It is not known whether the α -latrotoxin crosses the placenta. Reported cases of latrodectism in various stages of gestation have not led to spontaneous abortion [58, 59], although there are reports of spontaneous abortion after latrodectism in nineteenth-century southern Russia [58]. Antivenom is not contraindicated in pregnancy. One observational study showed no pregnancy losses in the 97 cases studied [60].

Special Populations

Pediatric Patients

Infants may present with inconsolable crying, restlessness, generalized rash, and poor feeding [5, 12]. There are a few case reports of priapism associated with *Latrodectus* bites in pediatric

Elderly Patients

Elderly patients have been said to be at increased risk of severe morbidity from latrodectism. Patients with comorbidities, such as ischemic heart disease, might be more susceptible to the physiologic stress resulting from the high catecholamine state associated with latrodectism. Profound dysphoria may be mistaken for altered mental state. Latrodectism itself may cause chest pain, but widow bites also have been associated with elevated markers of cardiac injury [26]. The incidence and significance of these changes are not known.

Key Points in Envenomation by Widow and Related *Latrodectus* Spiders

1. *Latrodectism* refers to envenomation by the widow spiders (genus *Latrodectus*).
2. Latrodectism is similar throughout the world. There is structural homology of the venoms of the various *Latrodectus* species.
3. The diagnosis is made on clinical grounds. It is based on a history of possible spider contact; local pain that migrates to other areas; autonomic changes, such as diaphoresis and hypertension; and pain or discomfort that appears disproportionate to physical signs.
4. Mortality is negligible with good supportive care.
5. Opioids and benzodiazepines improve patient comfort. There is little evidence to support the routine use of calcium gluconate or muscle relaxant agents, such as dantrolene sodium and methocarbamol.
6. Patients with symptoms refractory to a combination of opioid and benzodiazepine should be considered for antivenom therapy, especially in parts of the world where safe antivenom products are available.
7. Most patients may be discharged from the hospital after treatment with antivenom; admission to the intensive care unit is rare, unless there are unusual complications of envenomation or treatment.

8. Antivenom raised against one *Latrodectus* species is likely to be effective treatment for envenomation by other *Latrodectus* species.
9. Known equine allergy or previous exposure to horse serum should be addressed. Use caution in patients with asthma and history of atopy.

Botulinum toxin is the ultimate example of the core principle in toxicology that all substances are poisons, and it is only the dose that determines if a substance is therapeutic or toxic. Two forms of pharmaceutical products, onabotulinum toxin A (Botox) and rimabotulinum toxin B (Myobloc), are used as injectable therapeutic agents to induce local muscle paralysis to treat a growing variety of disorders from dystonia to bladder spasm, as well as cosmetic enhancer to flatten facial wrinkles. More botulinum-based products for these, and other, purposes are under development. As a toxin, botulinum, when ingested, is one of the most lethal on a weight per kilogram basis with a LD₅₀ of 0.001 ug/kg [1].

There are four *Clostridium* bacteria that elaborate a botulinum neurotoxin (Table 1). There are eight serotypes of *Clostridium botulinum*, designated A through H, and each produces a distinct neurotoxin designated BoNT/A through BoNT/H [2]. Subtypes of neurotoxins, which are differentiated by amino acid sequences, are designated by a number after the serotype letter for serotypes A, B, E, and F. Nearly all human cases of botulism are caused by *Clostridium botulinum* serotypes A, B, and E [3, 4]. Serotypes C and D produce disease in birds and livestock only. Occasional human cases of botulism type E, subtype E4 and E5, are caused by botulinum toxin from the anaerobic bacteria *Clostridium butyricum* [2, 5, 6], and very rare cases of subtype F7 toxin may be elaborated by *Clostridium baratii* [2, 7, 8]. Five cases of human disease from *Clostridium argentinense*, which

produce type G neurotoxin, have been detected at autopsy from a series of unexplained deaths in Switzerland [9]. Additional “bivalent” strains produce dual toxins with the prevalent toxin type designated by a capital letter and the lesser type by a small case letter: Ab, Ba, Af, Bf, and an equal dominant type AB [10]. Type H neurotoxin has recently been identified in conjunction with a type B case (Bh) in an infant [10, 11].

History

A mysterious paralytic disorder was first linked to poorly prepared sausages in the late 1700s in Germany. The first documented cases occurred in 1793 in the village of Wildbad, in Wurttemberg. A serious outbreak of food poisoning related to “Blunzen,” a dish of blood sausage cooked in a pork stomach was responsible for 13 cases of food poisoning, of which six persons died [6, 12]. A decade later in 1802, the first warning about eating sausages was issued by the Royal Government in Stuttgart, when health officials offered a list of symptoms that included vomiting, double vision, and dilated pupils as a guide to local health practitioners [6, 13]. Professor Johann von Autenrieth, at the University of Tubingen, suspected that sausages were not boiled long enough during preparation which

led to their contamination with an as yet unidentified agent. In 1817 he summarized seven cases sent to him by two practitioners [6]. Six of those cases were submitted by Dr. J. Georg Steinbuch on a cluster from liver sausage in the town of Herrenberg. The only other case was submitted by a Dr. Justinus Kerner, the medical officer in Welzheim [12]. Steinbuch died a year later, but Justinus Kerner continued to collect and publish these “sausage poisoning” cases that for many years in Germany would be called “Kerner’s disease.” Within 3 years, in 1820 Kerner had published a monograph with descriptions of 76 cases he had observed, with details of their symptoms [13, 14]. Two years later, Kerner had summarized details of the 155 cases of botulism he had attended [13]. Kerner tried to discover the basic science behind the mysterious disease. He prepared extracts of the food and treated them with silver nitrate, mercuric chloride, and ferric chloride. He then fed these preparations to a wide range of experimental species including birds, mice, rabbits, and cats [11, 13]. In each of these mammalian species, he observed what would be the cardinal symptoms of botulism: vomiting, dilated pupils, ptosis of the eyelids, difficulty swallowing, and respiratory failure. Finally, as was common among the medical pioneers of that era, he experimented with a small dose on himself and noted a similar weakness. He placed a drop of the extract on his tongue and observed it caused “a great drying out of the palate and the pharynx” [13, 15]. He tried a larger dose and noted his “eyelids became tired, his vision blurry,” and then he developed pain in his abdomen and constipation. When his mentor Professor von Authenrieth heard of Kerner’s dangerous self-experiments, he wisely persuaded him to stop these experiments [12, 14]. Kerner’s conclusions from these experiments were that the toxin develops under anaerobic conditions and affects the autonomic nervous system [15]. In somewhat prescient speculation, Kerner thought that someday this toxin could have a therapeutic use in suppressing hyperactivity of the sympathetic nervous system such as sweating or oversecretion of mucous [13, 15].

Toward the end of the century, in 1895 in the Western Wallonian district of Hainaut in Belgium, another cluster of botulism cases occurred. Emile Pierre Marie van Ermengem of the University of Ghent was sent to investigate. He was a student of the noted microbiologist Robert Koch and had worked in Koch's Berlin Laboratory in 1883 [12, 16, 17]. He would uncover the cause of botulism and provide accurate descriptions of the progression of the disease. This larger cluster of cases originated from a funeral wake where pickled raw ham had been served. Within a day, twenty-three friends of the deceased who had eaten the ham fell ill with abdominal pain and vomiting. Their vomiting persisted and stomach pains grew worse, but few had any diarrhea and many began to complain of constipation and sought purgatives as a cure [17]. By the second day, some had visual disturbances, "veiling of the eyes," and "loss of clarity of vision over" short distances [17]. The next day, the patients had double vision, their throats were dry, and they were choked with thick viscous mucus; no amount of coughing could clear it. Their voices grew dull and articulation became difficult, and then it seemed as if the "tongue itself was paralyzed" [17]. By the end of a week, three had died and 10 were seriously ill [16]. Notably, none of them developed a fever, and their thinking remained clear until weakness and difficulty breathing overcame them in the last few hours before death.

On van Ermengem's investigation, it was discovered that one ham, uncooked but pickled in brine, lay at the bottom of the barrel from which the food was served at the wake. It did not smell of putrefaction. After initial slide preparations proved negative, anaerobic cultures were done, and he discovered a large spore-bearing bacillus [17]. Staining with Ziehl's solution revealed oblong ellipsoidal bodies within the muscle bundles of the ham that proved there were spores present [17]. In experiments similar to Kerner's, van Ermengem cut the ham up into small pieces and fed it to mice, guinea pigs, rabbits, cats, dogs, chickens, and monkeys. The cats and monkeys experienced a syndrome identical to human botulism [17]. It was van Ermengem who proposed giving the name *Bacillus botulinus* to the

Clostridium-like bacillus he found. The spore-forming bacillus was named for the Latin word for sausage – botulus.

In 1904, G. Landmann examined another cluster of poisoning cases from canned beans. Twenty-one people who had eaten salad made from waxed beans at a German cooking school became ill, of these eleven had died [11, 18]. This was a unique but important event, as up to this point in time, it was assumed that botulism was a disease only of meat and, in scarce Russian literature, of fish. Working at the German chemical house of Merck in Darmstadt, Landmann was able to culture the anaerobic bacillus [19]. In 1910, Dr. J. Leuchs from the Royal Institute of Infections in Berlin obtained some of the original samples of the *Bacillus botulinus* from the van Ermengem strain and from Landmann's outbreak of canned white beans. He injected these bacilli into horses and from this equine source harvested sera producing an antitoxin [12]. He found that each antitoxin only neutralized the bacillus-produced toxin from the strain from which it was derived, suggesting that there were two different toxins involved. It was not until 1919 that Georgina Burke at Stanford University would designate the Landmann strain as type A and the Van Ermengem strain type B, designations that remain today [12, 19].

Biochemistry and Clinical Pharmacology

The pathophysiology in classic food-borne botulism occurs through the ingestion of the preformed botulinum toxin from food [1, 3, 19–21]. In the gastrointestinal tract, the botulinum toxin is actively transported across the lumen of the intestinal tract via endocytosis and transcytosis. Serotypes A and B are the most efficiently transported across the intestinal lumen [2, 22]. Once in the systemic circulation, botulinum toxin is distributed to sites of acetylcholine-mediated neurotransmission where it causes toxicity [20, 22]. The large molecular mass (15,000 Da) of the botulinum toxin renders it incapable of crossing the blood–brain barrier. Botulinum toxin inhibits cholinergic transmission at

sympathetic and parasympathetic ganglia, at parasympathetic postganglionic sites, and most importantly at the presynaptic cholinergic nerve terminal at the neuromuscular junction [22]. Anticholinergic symptoms tend to be mild, and victims will manifest dry mouth, dilated pupils, and decreased bowel and bladder motility.

All botulinum toxins consist of a linked heavy chain and light chain. The heavy chain binds to the presynaptic neuronal surface, where the toxin is taken up by endocytosis. From within the endocytosed vesicle, the light chain translocates from inside the vesicle into the presynaptic cytosol [2, 19, 22]. The light chain is cleaved from the heavy chain by reduction of a single disulfide

bond, in order to enter the neuronal cytosol, where it acts as a zinc-dependent endopeptidase. The light chain inactivates one of three SNARE proteins (soluble N-ethylmaleimide-sensitive fusion protein attachment receptor) in the neuronal cytosol [2, 19, 23] (Table 2, Fig. 1). The SNARE protein complex allows acetylcholine-

Table 2 SNARE protein inhibition by botulinum serotype

Botulinum type	Cytosol SNARE protein inhibited
A, E	SNAP-25
B, D, F, G	Synaptobrevin
C	Syntaxin and SNAP-25

Fig. 1 Botulinum neurotoxins (BoNT) prevent exocytosis by cleaving synaptic proteins. Synaptic vesicles (SV) approach the synaptic membrane and form the SNARE complex as a prerequisite for the fusion pore and exocytotic transmitter release. During this step, BoNT bound to gangliosides at the extracellular side can be taken up into the vesicle by binding of the heavy chain to specific target proteins synaptotagmin or SV2. Following retrieval from the plasma membrane, recycling vesicles

become acidified again by means of the vacuolar proton pump (V-ATPase). This results in incorporation of the N-terminus of the heavy chain into the vesicular membrane, partial unfolding, and translocation of the light chain into the cytosol to target the specific synaptic proteins involved in the exocytotic machinery (From: Current Topics in Microbiology and Immunology, Botulinum Neurotoxins, Synaptic Vesicle Proteins: Targets and Routes for Botulinum Neurotoxins, 2013)

containing vesicles in the presynaptic nerve terminus to fuse with the neural cell wall in preparation to be released into the synaptic cleft [1, 2, 4, 22, 24]. Both serotypes A and E inhibit the function of SNAP-25 protein, while serotype B inhibits synaptobrevin [2, 25]. Without the ability of acetylcholine vesicles to fuse and dock with the distal neural cell wall in the absence of functional SNAP-25, release of acetylcholine does not occur, and no muscular contraction can occur. The result is a progressive descending flaccid paralysis.

Clinical Presentation and Life-Threatening Complications

There are six clinical forms of botulism, three of which occur through the gastrointestinal route (Table 3).

Adult Botulism

All adult-type forms of botulism manifest symptoms similarly [1, 26–29]. The gastrointestinal forms usually have a prodrome of nausea and vomiting within a few hours of ingestion of a contaminated food source, but often it is not bothersome enough for most people to seek medical care. Diarrhea that occurs with other food-borne illnesses may not occur with botulism. A variety of food sources around the world have been implicated in food-borne botulism outbreaks [3, 26] (Table 4). Typically these foods have low acidity, low salinity, and were canned without adequate heating to kill the botulism spores, which are often introduced via soil contamination.

Onset of symptoms after exposure is variable, even within common source outbreaks, but with

Table 4 International foods associated with cases of botulism by country

Ashbal (salted carp eggs) – Iran
Canned Mushrooms – Russia
Chopped garlic in soybean oil – Canada
Chou dou fu (fermented bean curd) – China
Cinkrugan (fermented raw goat meat) – Taiwan
Faseikh (fermented mullet) – Egypt
Gefilte fish – US Jewish community
Hazelnut yogurt – United Kingdom
Heart of palms – Brazil
Inlagd sill (pickled herring) – Sweden
Izushi (fermented sole preserved in rice) – Japan
Kapchunka (uneviscerated salted whitefish) – Israel, Russian immigrants, United States
Kunzha (smoked fish) – Russia
Ladoo (sweetened flour) mixed with buttermilk curd – India
Mascarpone cream cheese, tiramisu – Italy
Matambre (rolled stuffed meat) – Argentina
Muktuk (whale blubber) – Alaska, United States
Octopus escabeche (pickled octopus) – Argentina
Olives – Spain
Pruno – US prison wine
Palani (surgeon fish) – Hawaii, United States
Rakfisk (fermented char) – Norway
Salchipapas (Fried potatoes, hot dogs, and eggs in mayonnaise) – Peru
Seal oil – Alaska, United States
Scallops – France
Skordalia (Baked potato in garlic oil) – Greek food, United States
Suzme yogurt – Turkey
Vacuum packed whitefish – Canada
White ants – Kenya

food-borne botulism onset of symptoms occurs usually within 1–5 days of ingesting the contaminated food product [26–29]. Type F cases may occur more rapidly within 48 h [7]. Once the botulinum toxin acts at the neuromuscular junction presynaptic nerve, signs and symptoms of a flaccid paralysis occur in a descending fashion. Bulbar palsies of the cranial nerves with motor function present first [29]. Initially it affects the oculomotor muscles, progressing to facial muscle paralysis and then to muscles of mastication, swallowing, and eventually the larger muscles of the arms and legs. Ultimately, if unrecognized and

Table 5 The twelve “D” s (Horowitz Dodecad): symptoms of botulism in order of appearance [21]

Dry mouth
Diplopia
Dilated pupils
Droopy eyes (ptosis)
Droopy face
Diminished gag reflex
Dysphagia (difficulty swallowing)
Dysarthria (difficulty articulating speech)
Dysphonia (difficulty phonating/whispered speech)
Difficulty lifting head
Descending paralysis
Diaphragmatic paralysis

A shortened version of this is taught in Alaska as the “pentad” [6]:
Dilated pupils
Diplopia
Dry throat
Dysphagia
Nausea and vomiting

untreated, the intercostal muscles and the diaphragm are compromised, and respiratory insufficiency occurs. Once allowed to progress to respiratory failure, the patient will need ventilator-assisted support, potentially for several months, until the motor end-plate recovers [30]. A constellation of symptoms called the dodecad or 12 “D” s has been used as mnemonic (Table 5).

Notably absent in this clinical presentation are any central neurologic manifestations or any sensory impairment. Since botulism is not an infection with *Clostridium*, but rather a manifestation of elaboration of botulinum toxin from its spores, fever is not part of the presenting symptoms. Even in cases of wound botulism, the wound does not always appear to have a significant inflammatory component, fever may be absent, and evidence of systemic infection, such as leukocytosis, may not be found [31].

The US Centers for Disease Control and Prevention (CDC) recognizes another adult gastrointestinal form, previously referred to as undefined adult botulism and also referred to as adult-type infant botulism, now classified as adult intestinal toxemia [32–34]. This very rare form of botulism

has a delayed onset from clostridial colonization in an abnormal gastrointestinal tract and may take 40–60 days for stools to clear. In a case series from Ontario, Canada, in 2006, two patients had Crohn’s disease and a prolonged course [33]. It has been associated with peptic ulcer disease, Billroth surgery, and Crohn’s disease [34].

Infant Botulism

Infant botulism presents differently from adult-type botulism. 95% of cases occur in children less than 6 months, and its occurrence after 1 year of age is rare [35–46]. Almost all cases are caused by *Clostridium botulinum* serotypes A and B. Case reports of *Clostridium baratii*, type F, and *Clostridium butyricum*, type E, have occurred [7, 8, 41–43]. An epidemiologic investigation initially linked infant botulism to parental feeding of raw honey to the infant [46], but since the initial reports most cases occur without being fed honey. Breast-feeding may be an unappreciated risk factor. Infants fed formula usually present within 2 months of life suggesting a narrow window of susceptibility, while breast-fed infants present up to 1 year old [37]. It is rare for an infant botulism case after 2 months old to not have been breast-fed [37, 43].

The pathogenesis is linked to the fact that infants have both immature intestinal flora and decreased bile acids that allow the *Clostridium* spores to colonize the bowel, germinate, and elaborate the toxin [44, 46]. Both the toxin and the bacteria can be obtained from fecal samples, sometimes requiring a saline enema in order to obtain a sample. Symptoms begin with bulbar weakness such as a poor suck or weak cry due to inhibition of phonation muscles and inability to hold the head upright [44]. Constipation in a young child is a prominent complaint of parents bringing a child to a clinic or emergency department for evaluation of an infant that ultimately is proven to have infant botulism [44]. This nonspecific presentation often causes misdiagnosis early in the natural course of the disease. As infant botulism progresses over a

few days to a week, a more generalized muscle weakness occurs with a hypotonic or “floppy” baby with poor head and neck control. A weak hoarse cry, ptosis, and diminished deep tendon reflexes all may be noted [44]. Most cases do not progress to respiratory failure; however, missed cases are speculated to be responsible for possible sudden infant death syndrome [38]. Once the diagnosis is considered, hospitalization is required in a pediatric intensive care setting, as secondary complications such as pneumonia and sepsis can occur [37, 38, 44]. Hyponatremia due to syndrome of inappropriate antidiuretic hormone release has been reported in hospitalized cases [36].

Wound Botulism

Wound botulism occurs when a wound is colonized with *Clostridium botulinum*. Early cases prior to the 1980s were often due to surgical wounds with retained packing [47]. After 1982, clusters of cases associated with injection drug users who had “skin-popped” black tar heroin appeared [31, 47–53]. On presentation, their injection sites did not have the appearance of wound infections and only displayed the typical scarring from multiple intravenous or intramuscular drug use. Some cases had asymmetric bulbar palsy on initial presentation, but progressed with symmetric descending paralysis [48]. Since food contamination was not the source of *botulinum* toxin, gastrointestinal symptoms were absent. Delays to diagnosis, especially early in a clustered outbreak, meant delay to administering the antitoxin and a prolonged ventilator-dependent clinical course [53]. The vast majority of the cases occurred in California, and the few others were all on the West Coast, where type A *botulinum* toxin was implicated [47–51]. In addition to the standard supportive care and early antitoxin administration, debridement of wounds is critical to management. It is frequent that such injection drug users have multiple wounds and all wounds should be explored for signs of necrotic tissue to

be debrided. Any signs of adjacent skin infection should be treated with antibiotics.

Inhalational Botulism

Inhalational botulism is a potential biologic weapon, but this form of exposure has only been described in humans after an accidental laboratory exposure [54]. Three days after performing an autopsy on a lab animal that died of botulism, three technicians developed tightness in the throat, difficulty swallowing, and symptoms characterized as a cold without a fever [54]. They developed ocular paresis, rotatory nystagmus, dilated pupils, dysarthria, ataxia, and generalized weakness. All recovered within 2 weeks with antitoxin treatment [54]. If a terrorist attack occurred with inhalation botulism, there would likely be an irritant upper airway prodrome with the initial contact, followed by a variable onset of different degrees of paralysis in exposed victims. By 3 days postexposure, those maximally affected might present to a variety of outpatient and emergency department sites with the classic syndrome of descending bulbar palsies. The issue which makes this scenario most worrisome is that delayed diagnosis in a large number of patients, and the limited availability of the antitoxin, would lead to a significant number of ventilator-dependent victims immobilizing intensive care unit (ICU) care for months.

Botulinum toxin had been investigated as a biologic weapon earlier by British, the US, Canadian, Japanese, and Soviet military since World War II. Japan’s infamous Unit 731 during World War II experimented with botulism by feeding it to prisoners in Manchuria [19, 54]. Botulism’s sole link to a purposeful use as a weapon is that it is thought that Paul Fildes, a high-ranking British specialist in bacterial weapons development during World War II, alluded to the fact that he contributed to the assassination of Reinhard Heydrich, head of the Gestapo [54]. The British supplied the Czech underground with a modified hand grenade, with a glass vial containing

botulism attached to it, that was used in the ambush of Heydrich's car.

As far as an aerosolized weapon, the Russians have exposed animals to botulinum toxin at their Vozrozhdeniye Island site in the Aral Sea [19]. In the early 1990s, prior to their attack with Sarin on the Tokyo subway system, the Japanese doomsday cult *Aum Shinrikyo* had released an ineffectively produced *Clostridium botulinum* preparation in Japan targeting a US military installation and planned a release during the prince's wedding [19].

During the United Nations inspections of Iraq's capabilities for biologic warfare in 1991 after the first Gulf War, botulinum toxin was found to be one focus where Iraqi research efforts had been directed. Iraq had produced more botulinum toxin than any other weaponizable agent. Approximately 19,000 l were produced of which approximately half was already loaded onto warheads [19, 55]. When General Hussein Kamal Hassan defected from Iraq in August 1995, he verified that he was personally aware of 100 bombs, 13 SCUD/Al Hussein missiles, and 122 mm rockets that were loaded with botulinum toxin as part of Iraq's biologic weapons program [54, 55]. As a response to these events, the US Strategic National Stockpile has the new botulism heptavalent antitoxin cached throughout the United States as part of their disaster and bioterrorism preparedness.

Inadvertent/Iatrogenic Injection of Botulinum Toxin

Therapeutic injection of botulism, as Botox or Myobloc, for the variety of motor disorders has on a few rare occasions resulted in local muscle toxicity. However, a bizarre event occurred in November 2004 when an osteopathic physician, who had previously had his license revoked but operated a cosmetic clinic in Florida, and his girlfriend were admitted to hospitals in New Jersey in ventilatory failure. Simultaneously another married couple – a chiropractor and his wife – who were treated at this physician's clinic were admitted to a different hospital in Florida

[56]. Investigation of this event revealed that the physician purchased large quantities of research grade botulinum toxin, not intended for human use. He then attempted to compound it on his own to a more dilute concentration equivalent to "Botox." Pharmaceutical Botox was not involved. All four victims ended up on ventilators for several months, with 3 of these cases confirmed as botulism [56]. This gap in the tracking of high-grade botulinum toxin highlighted a loophole in the surveillance of sale and distribution of this product, which could lead to its use as a terrorism agent, which theoretically could be dispersed as an aerosol.

Diagnosis

Differential Diagnosis

Although a long list of neurologic and metabolic causes for motor neuropathies is frequently considered [19, 21, 25, 27], only two important diagnoses seem to cause the majority of misdiagnosis of botulism and accordingly delay to treatment [21, 28, 57]. Myasthenia gravis is frequently considered in new onset bulbar palsies without sensory findings, especially when isolated bilateral ptosis is the presenting complaint. In fact the edrophonium challenge test, thought to be specific for myasthenia, may be equivocally positive in some botulism cases owing to its subjective interpretation [48, 58]. The other often considered diagnosis is the Miller Fisher variant of the Guillain-Barre syndrome. This is an exceedingly rare disorder, usually having a viral prodrome with fever and more likely would present with ataxia [59, 60]. Even if the Miller Fisher variant of the Guillain-Barre syndrome is considered in the differential diagnosis, treatment for the more common botulism should be started, as time to antitoxin administration is critical for botulism.

Hypokalemic periodic paralysis and tick paralysis, two other common causes of symmetric myopathies, predominantly affect the proximal large muscles rather than cranial nerves. Unlike botulism, tick paralysis usually presents as an ascending paralysis, sometimes with an initial

Table 6 The motor exam for bulbar palsies

CN III	Can't move eyes left and right, lids droop
CN IV	Can't look downward symmetrically
CN V	Can't bite down
CN VI	Can't look outward
CN VII	Can't close eyes against force, purse lips, or smile
CN IX	Stylopharyngeus muscle only
CN X	Diminished gag reflex and difficulty swallowing, saying "ah"
CN XI	Diminished strength trapezius and sternocleidomastoid
CN XII	Difficulty moving tongue side to side

ataxic gait. Some venomous snakes, mostly elapids (cobra-type) can cause a botulism-like descending paralysis, though usually of more rapid onset. A history of snakebite may not be available, as bites of some species may go undetected and bites to sleeping humans may result in a severely paralyzed patient by morning, with no clear history of snakebite; the latter is classic for krait bites in parts of Asia. The similarity between snakebite paralysis and botulism is not surprising, as some of the snake presynaptic neurotoxins share similarities in site and mode of action with botulinum toxin. Most other central neurologic lesions, such as strokes, carotid dissection, tumors, and trauma, present with unilateral findings and some degree of central symptoms such as altered level of consciousness.

A high clinical suspicion based on the motor exam should be all that is needed for the treating physician to initiate the request for the release of botulism antitoxin, which in the United States is from the CDC. A young person presenting with ocular muscle findings who has not suffered a cerebral vascular accident is most likely to have botulism [21]. Bulbar palsies of the cranial nerves usually involving cranial nerves III and VI are the most common early finding [21, 60] (Table 6). Notably absent in the clinical assessment is any change in mental status, sensory findings, tremor or motor hyperactivity, fever, leukocytosis, or electrolyte abnormalities.

An assessment of impending respiratory failure should include bedside pulmonary vital capacity or negative inspiratory force, which should be

assessed early and repeated frequently [21]. Adjunct monitoring with end-tidal CO₂ may also be a vital clue to impending respiratory compromise.

Depending on the suspected site of entry samples of stool, gastric content, serum, wound aspirates, or sputum may be sent in anaerobic transport media for culture of *Clostridium* species [20]. The samples ideally should be obtained before treatment with antitoxin. In the constipated infant botulism patient, a gentle saline enema may be needed to obtain a stool sample [44]. Early growth in the anaerobic culture media of the typical gram-positive bacillus suggests a clostridial species, especially if they have oval-shaped subterminal spores and beta-hemolytic activity [1]. Specimens should be handled with a biosafety level 2 containment in the microbiology laboratory [20].

In the United States, serum, stool, and suspected contaminated foods can be sent to the health department or the CDC for a mouse bioassay. In the event of a bioterrorist event, contaminated surface swabs should also be sent for a mouse bioassay or an ELISA test [61]. The mouse bioassay is the most widely utilized test by health departments. While crude in its design, it is considered the most sensitive test for the diagnosis of botulism. Either serum or a biologic fluid supernatant is injected intraperitoneally into two sets of mice, one set pretreated with botulinum antitoxin and a control group [10, 61]. In a positive test, the mice with the antitoxin pretreatment all live, and the untreated mice all die. A definitive result may take as long as 4 days [61]. Since there is a long turnaround time on this assay (not counting additional delays in transport to an appropriate lab), **treatment of the patient should be instituted on clinical suspicion** and never await the results of this assay, which is used only to confirm and to serotype the botulinum toxin involved [61]. The ELISA test is not available outside of research facilities but has a shorter turnaround time and may be as sensitive for detection of the botulinum toxin [61].

While awaiting the delivery of antitoxin, other ancillary tests may be helpful to eliminate other diagnostic possibilities. A complete set of

electrolytes should help exclude potassium and magnesium disorders. A computerized tomographic scan should help eliminate central nervous system tumors or bleeds, although a magnetic resonance (MR) image or a MR angiogram may be necessary to exclude a brainstem lesion. A lumbar puncture can be obtained if infectious or postinfectious etiologies are considered, and an elevated cerebral spinal fluid protein suggests the Miller Fisher variant of the Guillain–Barre syndrome [59]. If myasthenia gravis is considered, the edrophonium (Tensilon) challenge test may be administered with a saline injection given first and the time to fatigue of upward gaze timed and then repeated after slow injection of edrophonium. If ptosis unequivocally improves, myasthenia gravis may be considered, but false-positive tests have been reported in cases of botulism [28, 54].

Other adjuncts such as electromyography are best reserved until after treatment with antitoxin. Botulism causes brief small amplitude motor potentials on repetitive nerve stimulation at 20 to 50 Hz, with an incremental response to repetitive stimulation [49].

Treatment

As early as possible, based on history and physical exam, the treating physician should contact their local and/or state health department to report a suspected case and seek their assistance in acquiring the antitoxin as quickly as possible.

The trivalent antitoxin (against serotypes A,B, E) was once the mainstay of treatment in the United States [1, 4]. It contained 7500 IU type A, 5500 IU type B, and 8500 IU type E antitoxins [21] (see Box 1). An older formulation of a bivalent antitoxin against only A and B serotypes was also used [21, 62], and in Alaska and Canada, a monovalent type E antitoxin was available. A specific monovalent antitoxin against serotype F is also produced. All these antitoxins were officially retired on March 12, 2010 when the CDC announced the release of a new heptavalent botulinum antitoxin (HBAT, Cangene Corporation) that replaces previously licensed

Table 7 Composition of each single use vial of HBAT

4,500 IU anti-A
3,300 IU anti-B
3,000 IU anti-C
600 IU anti-D
5,100 IU anti-E
3,000 IU anti-F
600 IU anti-G

trivalent ABE, bivalent antitoxin AB, and investigational monovalent botulinum antitoxin E (BAT-AB and BAT-E, Sanofi Pasteur) [63]. HBAT thus became the only botulinum antitoxin available for adults in the United States, although requiring an Investigational New Drug (IND) protocol. The HBAT antitoxin is currently part of the American Strategic National Stockpile that is kept in cached quarantine sites in the United States at large hub airports. The current amounts of serotype-specific antitoxin in HBAT are listed in Table 7 [6].

The US Army originally developed this equine-derived heptavalent (A-G) antitoxin [63–65]. The retired funeral procession horse, First Flight, was used for production of this equine-based antitoxin between 1978 and 1992. In a report of a case of botulism type F in California in 2004, it was first released on a compassionate use basis [8]. In 2006, the US Department of Health and Human Services contracted with Cangene Corporation in Canada, which evolved from Connaught Laboratories, the original manufacturer of the older trivalent antitoxin, to produce a heptavalent antitoxin. The current product is designated HBAT. In earlier literature, the heptavalent antitoxin was sometimes referred to as a “despeciated” product but is in fact an equine-derived IgG immunoglobulin that has been cleaved by pepsin removing the antigenic Fc component and leaving the F(ab’)² botulism immune globulin fragments, with some Fab fragments [65, 66]. This product was first assessed in an outbreak of type E food-borne botulism in Egypt in 1991 [65, 66]. In the Egyptian outbreak, forty-five patients received the US experimental F(ab’)² fragment antitoxin, and 5 others received it with

other antitoxins. Of the 45 patients who only received the US experimental F(ab')² fragment antitoxin, 31 were interviewed in a follow-up, and only one case whose symptoms could be construed in retrospect as serum sickness occurred [64, 65]. None of the patients treated with this new antitoxin died, although the more severe cases that were responsible for deaths occurred earlier in the outbreak [65]. A second outbreak assessment of HBAT was made in 2006. Twenty doses of HBAT were used in the bamboo shoot-related outbreak of food-borne botulism in Thailand, as part of an international mobilization of botulism antitoxins, and were assessed to have a good safety profile [67].

The current recommended dose for HBAT for adult botulism of all types is a single 20 ml vial diluted 1:10 in normal saline and administered over 60 min for all age groups above 12 months [63]. It has been used in children; if weight is < 30 kg, the recommended dose is to use a percentage of the adult dose equal to twice the patient's weight in kilograms (HBAT package insert, Cangene Corp., Winnipeg, Manitoba, Canada). In the continental United States, the HBAT antitoxin is cached in quarantine sites at designated large hub airports. It is necessary to have the treating physician call the local health department who then must call the CDC botulism emergency operations center (770-488-7100) to authorize the release of this product. In Canada, the responsible agency is the Botulism Reference Service (613-957-0902).

Alaska is the one US state that uses a faster distribution system. An educational outreach for the health aide program in over 180 individual villages has stressed the diagnostic mnemonic of the "pentad" for suspecting a diagnosis of botulism [68] (Table 5). Suspected cases can be air-evacuated from the villages to several regional hub hospitals where the antitoxin is kept at the hospital pharmacy. To release the antitoxin for use on a patient, a call to the Alaska State Section of Epidemiology (1-800-478-0084) starts the process [68]. An outbreak in December 2014 due to seal oil consumption involving 25 patients in remote villages was successfully managed this way.

Adjuncts to the critical care treatment of the botulism patient include all the special features of caring for any patient with severe neurologic impairment without cognitive impairment. Early in the course, a means of communication should be established through whatever preserved body movements the patient may still have. A limited group of nurses who are aware of the patient's ability at communicating will perhaps ease the frustration and depression these patient's experience. Frequent inquiries as to pain and discomfort caused by body position are important. Anecdotal experience suggests that patients may have headaches that go unnoticed and can be debilitating. Although reverse Trendelenburg position to 20–25° has been advocated in patients not requiring intubation, the more important adjunct is frequent measuring of vital capacity in these individuals to see if intubation is required [1, 69].

Once paralysis occurs, a collaborative effort by nursing, physical therapy, and respiratory therapy is needed to try to prevent the risks of infection, ventilator mishaps, and nutritional depletion that these patients experience. In one early series, a surprising number of deaths were due to unrecognized ventilator malfunctions [69]. Nosocomial pneumonia, urosepsis, skin breakdown and decubitus ulcer infections, and stoma infections of tracheostomies are common once the patient becomes ventilator dependent. The anticholinergic effect of the botulinum toxin may also contribute to bladder atony and thick viscid mucus secretions [29]. Muscle wasting and nutritional depletion will ultimately be impediments to weaning from the ventilator. Daily physical therapy of all paralyzed muscle groups will aid in the patient's rehabilitation. Frequent turning of the patient to prevent skin breakdown and pressure effects of immobilization is also important.

Treatment of Infant Botulism

In the United States, there is a human-derived antitoxin that is used only for cases of infant botulism. Human Botulism Immune Globulin (H-BIG) is only available through California State Department of Health Services (Telephone

510-540-2646) [35]. This product is derived from plasmapheresis from human donors who have received at least five doses of the pentavalent toxoid vaccine, usually given to at-risk laboratory workers [35, 70]. Since this is a pentavalent immune globulin against types A,B,C,D,E, it does not cover the rare occurrence of infant botulism serotype F disease [35, 41]. BabyBIG, as the US Food and Drug Administration (FDA) approved product is called, has a long biologic half-life and a greatly decreased risk of hypersensitivity reactions [35]. A single dose is given IV without any repeat dosing recommended. While potentially it could be used for adults who had an early and severe anaphylactoid reaction during the infusion of the equine-derived HBAT antitoxin preventing a full dose from being administered, it has never been released for this indication.

Botulism Vaccines

The Soviet-era biological weapons program experimented with a botulism vaccine in the 1930s and had the first human trials at the Vaccine-Sera Laboratory in Vlasikha in 1934 [71–74]. A bivalent vaccine was developed in 1946 (against types A and B) by the US Department of Defense, and C.E. Rice developed a similar vaccine in Canada in 1947 [72]. Subsequently, a pentavalent botulinum toxoid (PBT) vaccine was developed by at the US Army Medical Research Institute of Infectious Diseases (USAMRIID) in 1957 at Fort Detrick and manufactured by Parke-Davis between 1958 and 1981 [19, 73]. Since 1978, a comparable vaccine, from five monovalent vaccines, was produced by the Michigan Department of Public Health [19, 72–74]. It is effective in producing immunity in vaccinated laboratory workers against serotypes A to E. (It is not effective against F and G.) The original dosing schedule was three subcutaneous injections at 0, 2 weeks, and 12 weeks with subsequent annual boosters, based on antitoxin titers. Prior to 1969, fifty individuals who received this vaccine and were subsequently accidentally exposed to botulism did not develop any clinical symptoms of the disease [19, 72]. Between 1998

and 2000, the Michigan Department of Public Health monitored titers at 6 months after the three-dose immunization schedule and found they varied from a low of 19% for type E to 60% for type B and C [72, 74]. In a similar study at USAMRIID, type E titers were inadequate in 80% of vaccinated individuals with a three-dose regimen and in 60% with a four-dose regimen [73, 74]. Since titers against only types A, B, and C achieved an adequate level in greater than 50% of those vaccinated, the dosing regimen was changed to add a 6-month and 12-month booster vaccine dose, and since 2004 the recommended regimen is a five-dose schedule at 0, 2 weeks, 12 weeks, 24–26 weeks, 1 year, and annually thereafter [19, 73].

The pentavalent PBT was used in over 20,000 laboratory workers and in 8,000 soldiers deployed in the Gulf War [73]. Moderate local reactions occur in 7% of healthy vaccine recipients, and severe local swelling greater than 120 mm or lymph node swelling occurs in less than 1–2% [74]. Systemic reactions of fever, malaise, headache, myalgia, neck or back stiffness, hives, or pruritus occur in 5% [73, 74]. The pentavalent vaccine was not approved by the FDA and was part of the Strategic National Stockpile. It was retired from use in November 2011 due to loss of antigenicity of existing stocks, but persons in the middle of a vaccination series were allowed to complete it by May 2012 [75]. Individuals who have received the full five-dose vaccination schedule and have adequate titers are the source for BabyBIG [72–74]. Since the immunogenicity of the PBT vaccine is declining as subsequent lots are produced, research continues into candidates for a replacement vaccine. Japan has developed a tetravalent vaccine against all the human disease-causing serotypes, A, B, E, and F, but its immunologic response declines by 90% at 9 months after a 3-dose regimen [71]. Investigations of recombinant vaccine products, based on an immunologic response to the C-terminal end of the botulinum heavy chain (Hc), are underway at USAMRIID. The bivalent recombinant anti-AB vaccine based on this technology has shown good titer response and safety in phase I human trials and is in phase II trials [74].

Prognosis

Delay to administering the antitoxin is the most important factor affecting clinical course and outcome. In one study, mortality was 10% in those who received the antitoxin within 24 h of onset of symptoms, 15% when it was administered later than 24 h, and 46% when not given at all [76]. However, these statistics must be tempered within the time period when the data occurred, as four out the 19 deaths in this series occurred due to ventilator malfunction or accidental extubation. The fatality rate in those over 60 years of age was twice that of those patients younger than 60 [76].

The more rapid the onset, the more likely intubation was needed [57, 77]. Type A patients typically have a faster onset than type B. In a review of CDC cases in 1999 and 2000, 83% of type A required intubation, where as only 33% of each type B and E required intubation [27, 57]. In another study, the mean time on a ventilator was 58 days for serotype A cases and 26 days for serotype B cases [27]. Ventilator dependence can last as long as 142 days [29].

When there is an outbreak, usually the index case is most severely affected and may have early misdiagnosis and hence delay in treatment [62]. Subsequent cases, once the clinical suspicion is raised in outbreaks, uniformly do better [78].

Delays in access to the antitoxin on the continental United States are often a result of the need for clearance from the CDC, before the antitoxin is released. Additionally antitoxin is not kept in health-care facilities, but rather is cached in nonhospital storage facilities at major airports. This cumbersome process to access the antitoxin has resulted in delay to administering it to patients and in longer hospital stays [6, 53]. In the United States, the next logical step to reduce delays to treatment would be to adopt a distribution plan similar to Alaska's for the rest of the country and have this product available in major hospitals.

It is difficult to compare outcomes between studies that have spanned many decades as substantial improvements in critical care have

reduced the mortality in cases once the disease is recognized and treated appropriately. One group which studied long-term follow-up indicated that normal pulmonary function is regained, but diminished respiratory muscle function and easy fatigue may persist in some patients at 2 years after recovery [69, 77].

The prognosis for recovery from infant botulism is excellent with supportive care. There has been a 20-year study and a 30-year study of infant botulism conducted at a single children's hospital [79, 80]. All 66 children survived, both before and after the time period when BabyBIG was utilized, although mean length of stay was reduced from a mean of 36 days to 15 days, once BabyBIG was available after 1990 [80]. Type A serotype caused longer lengths of stay and slightly longer, but not statistically significant, ventilator-dependent days than serotype B [79]. All children had normal neurologic function on follow-up. In the largest study of infant botulism with 122 children randomized to treatment with or without BabyBIG, the BabyBIG-treated cases had a mean length of stay of 2.6 weeks compared with 5.7 weeks in the non-BabyBIG-treated cases [35]. This translated into fewer days in the ICU, fewer ventilator-dependent days, fewer tube-fed days, and lower costs for the BabyBIG-treated cohort [35]. The only side effect was a single case of a transient rash.

Box 1: Older Antitoxins [81]

The trivalent antitoxin (against serotypes A, B, E) was the mainstay of treatment in the United States and Canada from 1969 to 2010. It contains 7500 IU type A, 5500 IU type B, and 8500 IU type E antitoxins. Production of trivalent antitoxin ended in 2001, as adequate levels of antitoxin E in the production process could not be assured, but existing stores continued to be used. From 2001 to 2010, most cases in the United States were treated with the FDA-approved bivalent antitoxin against only types A and B. However, in Alaska, a monovalent type E antitoxin had been available from Canada and was used along with the bivalent

(continued)

FDA-approved antitoxin with an IND protocol in Alaska until 2010. Type E antitoxin is rarely used by itself. It was first manufactured at the University of Toronto by Connaught Medical Research Labs and used experimentally in Hokkaido, Japan, in the 1950s and 1960s and in Labrador in the 1961. The case fatality ratio after type E antitoxin was instituted in Japan fell from 29% prior to the availability of the type E antitoxin to 3.5% in 85 patients treated with the type E antitoxin. Shortly after the initial success of the Canadian antitoxin in Japan, the Japanese National Institute of Health created their own type E antitoxin.

Dosing recommendations for the trivalent or bivalent antitoxin are to give a single vial diluted 1:10 in normal saline intravenously over 30–60 min.

Indications for ICU Admission

All suspected cases should be considered for ICU admission for observation of neurologic progression and frequent assessments of pulmonary vital capacity.

Criteria for ICU Discharge

Stabilized respiratory status. Some patients may be discharge to skilled facilities where specialized ventilator-dependent patients receive care.

Otherwise, patients will need to be extubated and demonstrate adequate respiratory functional capacity on repeat assessments.

Key Points

1. Botulism is a neurologic disease caused by the botulinum neurotoxin.
2. Food-borne and wound botulism predominate in adults.

3. A clinical finding of symmetric cranial nerve palsies in an adult should raise the suspicion for the presence of botulism.
4. HBAT antitoxin should be administered based solely on clinical findings and not await confirmatory assays or EMG testing (II-3).
5. In the United States, the CDC botulism emergency operations center telephone number is (770-488-7100).
6. Infant botulism is the most prevalent form of botulism in the United States, but it should be considered a separate entity characterized by subtle findings of poor feeding and muscle weakness.
7. Suspicion of a case of infant botulism requires treatment with BabyBIG (II-2), obtained from the California State Department of Health Services (510-540-2646).

Treatment Recommendations and Level of Evidence

1. Use of HBAT for adult and wound botulism: II-3
2. Use of BabyBIG for infant botulism: II-2
3. Use of HBAT for iatrogenic botulism: III
4. Use of HBAT for adult intestinal toxemia botulism: III

Hymenoptera is a large order of the class Insecta and comprises the social honeybees (family Apoidea), wasps, hornets, yellow jackets (Vespoidea), and ants (Formicidae). Honeybees (*Apis* species) are social insects that live in well-organized communities and have received more attention due to the massive attacks these insects can provoke. The species *Apis mellifera* includes several subspecies, with *A. m. mellifera* and *A. m. ligustica* being the most common in Europe and *A. m. scutellata* in Africa [1].

African honeybees were introduced into Brazil in 1956 with the aim of developing a strain better adapted to South American conditions than the European forms. However, in the following year, swarms of African bees escaped from a research facility in Rio Claro in the state of São Paulo and hybridized at random with the local European bees, forming the so-called Africanized bees [2] (Fig. 1). This accident dramatically changed the incidence and pattern of massive bee attacks in the American continents.

Although the Africanized and the European bees are similar in appearance [3], the former are peculiarly aggressive, attacking in swarms with high tenacity after minimal provocation [4]. They are able to sting using a modified ovipositor found on the terminal end of their abdomen (Fig. 2). After stinging, the stinger and the venom sac (Fig. 3) are pulled out of the bee's abdomen and remain in the victim's skin. The sting occurs only once and the insect dies following the evisceration.

Fig. 1 Africanized bee specimen from São Paulo, Brazil

Fig. 2 Bee stinger

Africanized bees rapidly spread throughout the American continent [5] and reached the USA (Texas, New Mexico, Arizona, and California) in the early 1990s [6–8], where their aggressiveness earned them the name “killer bees” [9, 10].

Massive bee envenomation is a public health issue in many countries in the Americas (South, Central, and North America). However, since reporting of beestings generally includes both allergic reactions to beestings, often from solitary stings, plus massed beesting attacks, with the former likely to be a significant majority of the total case load, such statistics cannot be easily separated and should be interpreted as an indirect evidence of the frequency, or rising frequency, of massed beesting attacks.

Most deaths are associated with few stings and occur as a result of immediate hypersensitivity

Fig. 3 Stinger and venom sac, pulled out of the bee

reactions (Type I) causing anaphylaxis. Severe local reactions, particularly those involving airway swelling and obstruction, may also be a cause of death.

Bee Venom

The venom apparatus of honeybees has an important role in the defense of the colony. Pheromone secretion is one of the main stimuli for inducing aggressive attitude in bees and guiding other bees to the victim. The quantity of venom protein released in a sting ranges between 50 and 140 μg [11], so an attack with 500–1,000 stings would deliver approximately 0.7–1.4 mg/kg of venom in an individual of 70 kg. The bee venom consists of several powerful allergens and pharmacologically active compounds, including a complex mixture of biologically active components, primarily enzymes, peptides, and amines, with some variability in toxic components between different colonies and species [12].

Phospholipase A_2 (PLA $_2$) is one of the major allergenic components of bee venom and is an enzyme that represents 10–12% of total venom [13]. It is able to destroy phospholipids, disrupting the integrity of lipid bilayers and thereby making cells susceptible to further degradation. Phospholipase A_2 also produces a series of pharmacological effects: contraction of smooth muscles, lowering of blood pressure, increase of

capillary permeability, and destruction of mast cells [14]. The synergistic action between phospholipase and bee venom melittin results in tissue damage to erythrocytes and mast cells. Phospholipase B, also known as lysophospholipase, another enzyme constituting only 1% of the venom, acts in combination with PLA₂ to destroy membrane phospholipids.

Bee venom hyaluronidase causes changes in cell permeability by altering cell membranes and disrupts collagen, thereby allowing other venom components to penetrate into the victim's tissues; it is also called the "spreading factor."

Melittin is the major component of bee venom, representing 50% of dry venom. It acts as a detergent disrupting cell membranes and liberating biogenic amines and potassium. Melittin is a protein that hydrolyzes cell membranes, alters cellular permeability, and causes histamine release. Phospholipase A₂ and melittin act synergistically, breaking up membranes of susceptible cells and enhancing their cytotoxic effects which are responsible for intravascular hemolysis and rhabdomyolysis [15]. It is also considered the constituent chiefly responsible for local pain because of the release of lysosomal enzymes from leukocytes, serotonin from thrombocytes, and histamine from mast cells [13]. Melittin has been studied in preclinical phases for its potential therapeutic application as an antiarthritis and pain reliever agent, as well as its antimicrobial and anticancer effects on different types of tumor cells and human peripheral blood lymphocytes [16, 17].

Peptide 401 (or mast cell degranulating peptide) causes mast cells to degranulate, releasing histamine and vasoactive amines, which may contribute to the toxicity of bee venom. However, in mouse models the lethality of bee venom does not appear to require this action.

Apamin is a neurotoxin that acts on the spinal cord. When injected into mice (≥ 1 mg/kg), animals develop uncoordinated, uninterrupted movements and generalized convulsions [15]. This action has not been correlated with any clinical symptomatology observed in patients suffering Africanized bee envenomation.

Bradykinin acts as an agonist on B₂ receptors, participating in vasodilatation via the release of

prostacyclin and nitric oxide, contributing to hypotension.

Adolapin inhibits prostaglandin synthetase and has anti-inflammatory actions; it has been postulated that it may be useful in the treatment of arthritis.

Histamine represents only 0.1–0.5% of the total venom but plays an important role in the inflammatory response by increasing permeability of capillaries. The catecholamines dopamine and norepinephrine enhance venom circulation by increasing heart rate. Serotonin is an irritant and contributes to pain caused by envenomation [15].

With the complete sequencing of its genome, the honeybee is now a preferred model organism for Hymenoptera species for venom characterization. Using a proteomics approach, most previously characterized venom proteins have been confirmed, and several new proteins and peptides have been described. Some of these constituents are of immunological significance [18–22].

Pathophysiology

A mouse model of subcutaneously injected venom, melittin and PLA₂, induced several pathophysiological alterations are observed precociously, such as local swelling, slower breathing, piloerection, and local muscle spasms. Coagulation disturbance is moderately observed, with enlargement in prothrombin and partial thromboplastin times and decrease in fibrinogen levels. Biochemical parameters are elevated, such as serum ALT and AST, creatine kinase (CK), creatinine, and urea nitrogen, indicating an acute liver, red blood cells, and skeletal muscle injury. The myotoxic effect of venom, PLA₂, and melittin may be demonstrated by CK increase induced by either PLA₂ or melittin and more potently by the whole venom [23]. Systemic damaging effect of very early onset on microscopic examination of the skeletal muscle shows early extensive damage in rats envenomed by Africanized bee venom. Rhabdomyolysis associated with diffuse acute inflammatory processes and vascular congestion

and increased creatine kinase levels are observed [24].

Renal histology of animals inoculated with bee venom shows acute tubular necrosis and massive tubular deposition of myoglobin [25], indicating that vasoconstriction, direct nephrotoxicity, and rhabdomyolysis are important mechanisms in the pathophysiology of bee venom-induced acute kidney injury (AKI), potentiated by the presence of hemolysis or hypotension following anaphylaxis or low cardiac output [26]. During rhabdomyolysis, the skeletal muscle is damaged, and CK, myoglobin, LDH, and AST are released into the blood and later into urine. Myoglobin may cause AKI by toxic effects on the tubule epithelial cells or inducing intratubular cast formation. The presence of myoglobin in the tubular casts, demonstrated by immunohistochemical analysis [27], reinforces the role of rhabdomyolysis in the progression of AKI after bee envenomation. In addition, myoglobin and hemoglobin are potent inhibitors of nitric oxide bioactivity and may trigger intrarenal vasoconstriction and ischemia in patients with borderline renal hypoperfusion. Renal ischemia may also occur as a consequence of a large release of norepinephrine. This may also contribute to ischemic lesions and myocardial infarction, further affecting cardiac output and causing renal ischemia [27].

Human postmortem histopathologic analysis confirms the occurrence of acute renal tubular necrosis in patients suffering hundreds of bee-stings in whom systemic rhabdomyolysis and intravascular hemolysis were observed [28–32]. Hemoglobin and myoglobin pigments, as well as erythrocytes, were found in the tubules and collecting ducts in these decedents. Thus, renal damage may involve both direct tubulotoxicity and prerenal factors such as hypotension. Generalized rhabdomyolysis and massive myoglobinemia and myoglobinuria are evidenced by increased CK levels, predominantly the CK-MM isoenzyme. Intravascular hemolysis is also a major feature of massive envenomation. Elevated serum indirect bilirubin indicates hepatocellular necrosis attributable to ischemia [28]. A toxic effect on the myocardium has been

demonstrated by the observation of necrotic cardiac myocytes [30]. Three mechanisms may be involved in the injury of myocardial cells: (a) IgE-dependent hypersensitivity reactions to venom and the vasoconstrictive effect of mast cell mediators, (b) direct toxic effects of venom, and (c) therapeutic epinephrine injection causing a decrease in coronary perfusion [33, 34].

Clinical Presentation

Bee envenomation results in a wide spectrum of clinical abnormalities, depending on the number of stings per body weight, time elapsed between the envenomation, and medical care, age, and comorbidities of the patient.

All envenomed individuals may present with some degree of local and regional reactions as a consequence of massive bee envenomation. Local pain, pruritus, erythema, and swelling at the sting site (Fig. 4) may evolve to a larger, regional reaction, mediated by allergic mechanisms and affecting parts of the body in continuity with the sting site.

A more severe type of reaction is a systemic anaphylactic response, characterized by varying degrees of urticaria, angioedema, nausea and vomiting, diarrhea, and intestinal or uterine cramping. More severe systemic reactions may include bronchospasm, laryngeal edema with inspiratory stridor, hypotension, dyspnea, loss of consciousness, cardiac collapse, and shock. Individuals who have specific IgE antibodies to allergenic components of bee venom are more susceptible to systemic reactions occurring within a few minutes of the sting.

Cases with >50 stings may develop systemic toxic reactions [35], although most cases are described in patients stung by hundreds of bees. Within 24 h post-sting, the patient may complain of generalized aches and pains, followed by brown-colored urine, as the result of rhabdomyolysis and hemolysis [28, 36–38]. Progressive increases in enzymes released from ruptured skeletal myocytes, such as CK, are seen in more than 90% of cases [30, 39]. Enzyme concentrations

Fig. 4 Male, 64 years old, stung by >500 bees, developed rhabdomyolysis and acute renal injury, recovered after supportive treatment

typically peak within the first 48 h and may be as high as 70,000 IU/L. Concentrations of other enzymes such as AST, ALT, and LDH may also be affected.

Although hemolysis also plays a role in the physiopathology of massive bee envenomation, less than 50% of patients present with jaundice or have clinical findings compatible with hemolysis [39].

Adrenergic manifestations (tachycardia, hypertension, diaphoresis, hyperthermia) are often described [40]. Cardiac involvement causing severe effects has been described in consequence of vasospasm, platelet aggregation and thrombosis, direct toxic effect, and Kounis syndrome (anaphylactic reaction). Clinically patients present atrial flutter, atrial and ventricular fibrillation, cardiomyopathy and acute coronary syndrome, ischemic stroke, and myocardial infarction [33, 41–44].

Besides infarction, reported neurological complications include encephalomyelitis, hemichorea, optic neuritis, and posterior reversible encephalopathy syndrome [43, 45–49].

Acute Kidney Injury

Acute kidney injury is a potentially life-threatening complication of massive attack by Africanized bees, especially when the patient is inflicted by 500 stings or more [28, 40, 50–52]. In

such conditions or cases, patients with AKI are unable to adequately excrete myoglobin and hemoglobin and may develop severe nephrotoxicity.

Acute kidney injury is often observed 24–72 h after envenomation [39, 52, 53], presenting with decreased or no urine output [39, 54]. Late-onset AKI has been described as a Type III hypersensitivity reaction (“serum sickness”) due to bee venom [55]. Most cases are described in elderly patients and those with underlying compromised renal function. However, children may develop AKI after 100–200 stings [56, 57], especially with late onset [58]. The duration of AKI varies from one to several weeks and is prolonged in elderly patients and those with underlying compromised renal function.

Serum blood urea nitrogen (BUN) and creatinine measurements are elevated, but do not correlate with the number of stings [37]. Besides elevation of muscle enzyme levels, myoglobinuria, and hemoglobinuria, other laboratory findings include hyperkalemia, hypocalcemia, and hyperphosphatemia [52, 56, 59].

Typically, renal function will recover, but there may be residual kidney damage [60].

Non-allergic patients attacked by swarms of bees may die as a result of the same manifestations seen in hypersensitive victims or as a consequence of systemic envenomation. The lethality rate is estimated to approximate 16%, including allergy and envenomation [39]. The median lethal dose of

honeybee venom has been estimated at 19 stings per kg or about 500 stings for adults [9, 11].

Children are at heightened risk for the effects of massive envenomation because of the larger dose of venom per kilogram body weight they receive [61], although patients older than 60 are mostly described in the severe group with higher lethality, making older age and previous kidney injury negative prognostic factors [39, 62].

Laboratory Findings

Hematologic findings of massive bee envenomation include leukocytosis with neutrophilia, which can be related to the toxic hematological and proinflammatory effects of bee venom.

In the first 24–48 h, muscle tissue enzymes (CK, AST, ALT, and LDH) rise. Total bilirubin also increases, primarily the indirect form, free hemoglobin in plasma increases, and haptoglobin decreases. The increase may persist until approximately the fourth day post-sting, with decreases from the fifth day onward [30].

Thrombocytopenia has been described, with or without coagulation changes such as prolonged or incoagulable whole-blood clotting time, international normalized ratio, activated partial thromboplastin time, and thrombin time. Serum BUN and creatinine concentrations should be assessed to monitor kidney function.

Whole venom and venom PLA₂ concentrations in serum and urine at intervals after massive bee envenomation have been quantified by enzyme immunoassay [28]. In one case, the highest whole venom antigen concentration detected on admission to hospital (3.8 µg/mL) was used to estimate the total amount of circulating venom (27.36 mg) and to estimate the number of stings received (>1,000).

Initial Management

After immediately stabilizing the airway, ventilatory requirements and assuring adequate tissue perfusion, the number of stings, allergic status, body size, historical information regarding insect sting allergy, previous cardiovascular or pulmonary diseases, and baseline renal function should be initially evaluated.

If time permits, removal of stingers still in the skin should be done as soon as possible (Fig. 5), either using a flat surface or pinching the stinger sac. Stinger removal is important to avoid further injection of the remaining venom after the bee has pulled away, although the stinger may deliver its venom content within 60 s of the sting [11, 63]. Thus, it may not be possible to remove the stingers within the time that it takes for them to empty the contents of the venom sac.

Victims must be observed closely as anaphylaxis can cause rapid clinical deterioration without

Fig. 5 Dead bees and stingers removed from the patient

warning. Cardiac monitoring, supplemental oxygen, and invasive airway management equipment must be readily available.

More severe regional reactions, and those involving multiple stings, can be initially treated in the same manner as small local reactions. However, we recommended that patients suffering from >50 honeybee stings be hospitalized and monitored closely for new onset or progression of the envenomation syndrome. Renal failure or death may occur in the range of 150–1,000 bee stings.

Treatment

The therapeutic approach to massive bee envenomation includes measures for treatment of hypersensitivity, preferably within the first hour. In cases of severe anaphylaxis, early aggressive monitoring, treatment, stabilization, and intervention are mandatory. Death may ensue quickly if the anaphylactic reaction is not managed expeditiously and appropriately. Once diagnosed, epinephrine should be given intramuscularly or subcutaneously immediately, in adults 0.2–0.5 mg of 1:1,000 solution (1 mg/mL) and children 0.01 mg/kg or 0.01 mL/kg of 1:1,000 solution (1 mg/mL). Administration may be repeated every 5–15 min as clinically indicated. For severe anaphylaxis epinephrine must be administered intravenously, in which case it must be diluted to a concentration of 1:10,000 and 0.5–1.0 mL given in adults and 0.01 mg/kg (not exceeding 1 mg) in children.

Vigilant monitoring of heart rate, heart rhythm, and blood pressure is required. Intravenous fluids are crucial to prevent vascular collapse and shock. Volumes of crystalloid solutions must be given rapidly in anaphylaxis.

Corticosteroids may benefit victims of massive bee envenomation. We recommend prednisolone sodium succinate 10 mg/kg IV, followed by prednisolone orally at 1 mg/kg bid, then tapered over 3–5 days. Intravenous infusion of saline is indicated if hypotension is present and to ensure sufficient urine output. For severe reactions, administration of fluids and electrolytes,

correction of hypovolemia, and prevention of inadequate circulation are the cornerstone of therapy. Toxic reactions to massive envenomation from multiple stings require early aggressive stabilization and therapy with fluids and may require vigilant monitoring of hematologic, cardiac, respiratory, and renal parameters for several days. Supportive therapy may be necessary until clinical stability is present. Prazosin may be used for control of hyperadrenergic states.

Dialysis is often necessary and recovery from AKI may take several weeks. Some renal damage may remain, especially in elderly patients. Rarely, conventional hemodialysis may not effectively remove myoglobin. In these cases, plasmapheresis [64] and continuous venous-venous hemofiltration [65] have been advocated.

Therapeutic Antibodies

There is an urgent need to develop antivenom to provide an effective therapeutic tool for victims of bee envenomation. In the past, an ovine bee Fab-based antivenom was produced with positive neutralization results against PLA₂ and European bee venom lethality, tested in mice [66]. However, no additional follow-up data on this antivenom has been reported. Separately, a rabbit antivenom against PLA₂ and melittin was shown to be ineffective in neutralizing venom lethality [3].

More recently, a horse antibody F(ab')₂-based antivenom was produced at our institute (Instituto Butantan) [67]. Adult horses were immunized by intramuscular injection of a mixture of 5 mg of bee venom (provided by the apiary of the Biosciences Institute of the Universidade Estadual de São Paulo, Rio Claro, southeast Brazil) and incomplete Marcol-Montanide-Tween 20 adjuvant. The obtained plasma was fractionated by adding ammonium sulfate and digested by pepsin, according to a preestablished protocol to isolate F(ab')₂ fragments and following the recommendations of the World Health Organization [68].

The antivenom obtained was effective in neutralizing *in vitro* hemolysis, myotoxicity, and hyaluronidase activity, induced by bee venom. The hemolytic action caused by 1 mg of bee

venom was neutralized by 2.4 mL antivenom (20.8 mg protein/mL). The antivenom neutralization of myotoxicity in vivo was measured by the release of creatine kinase in mouse muscle, and the effect was evaluated by morphological analysis and by monitoring the increase of plasma creatine kinase (CK) activity. The specific antivenom was able to completely neutralize the myotoxic effects and was not harmful when injected undiluted in mice [24].

To assess antivenom efficacy, we determined the effect of the neutralization antivenom on the LD50. The lethal potency of bee venom i.v. injected was 4.2 ± 0.2 µg/g of body weight. In mice, the lethal action caused by 1 mg honey venom was neutralized by 0.9 mL antivenom meaning ED50 is 1.11 mg/mL antivenom. In a case of massive bee attack involving 1,000 stings, which is considered potentially lethal for a 70 kg adult individual, it is estimated that 90 mL (9.9 mg) of antivenom would be needed to neutralize the venom effects. Scaling up the production is ongoing so as to provide antivenom for clinical studies and to assess the potential efficacy and safety of this new antivenom.

Another approach involves the production of human monoclonal single-chain Fv(scFv) antibody fragments as an alternative to inhibit systemic effects of bee venom, although studies of the neutralizing capacity of this possible antivenom are still necessary [69, 70].

The events of 2001, including the terrorist bombing of the World Trade Centers and the deliberate introduction of anthrax spores into the US postal system, marked a watershed in the medical planning for and response to an incident using a chemical or biologic weapon. Although much planning has focused on the prehospital and emergency department phases of these disasters, toxicology and intensive care are among the key resources in the management of the actual uses of these weapons.

Despite the popular notion of the inevitability of the threat posed by the terrorist use of chemical and biologic agents, few systematic scientific studies of mitigation efforts appropriate for civilian use have been published in the open literature. There is a paucity of systematic investigations in these areas and the majority of evidence is observational or expert consensus (level of evidence III). An Institute of Medicine study outlined priorities for research to improve the civilian medical response to terrorist incidents [1]. (level of evidence III). More recently an international task force drafted a series of consensus statements comprehensively covering the care of the critically ill in the setting of pandemics and disasters [2]. (level of evidence III). Successful management of an incident involving these weapons requires the coordinated efforts and response of a multidisciplinary team of fire, law enforcement, and medical and public health professionals and an emergency response at the federal, state, regional, and local levels. In the medical community, expertise in toxicology, emergency

medicine, critical care, infectious diseases, and public health is required to successfully manage the medical response to these incidents. This chapter focuses on the planning for and the medical management of the severely intoxicated victims of a chemical or biologic incident.

Framing the Problem

Terrorism has many different definitions and can manifest in many different forms and venues. The US Federal Bureau of Investigation defines terrorism as “Involv[ing] acts dangerous to human life that violate federal or state law [and] appear intended (i) to intimidate or coerce a civilian population; (ii) to influence the policy of a government by intimidation or coercion; or (iii) to affect the conduct of a government by mass destruction, assassination or kidnapping” [3]. The use of a chemical, biologic, radiologic, or nuclear (CBRN) weapon as a component of a terrorist act is an extremely rare event worldwide. The vast majority of terrorist incidents in the United States have involved conventional explosives. Because most non-scientifically trained people do not understand chemical and biologic agents, they appeal to the public’s psychological fear of destruction by a powerful, imperceptible force. This fundamental fear of destruction, coupled by the intense media attention surrounding a CBRN event, fulfills the need for attention to the cause espoused by the terrorist.

Misconceptions About Chemical, Biologic, Radiologic, or Nuclear Planning

1. Medical management of a terrorist use of a CBRN weapon is the same as the medical management of a military use of a CBRN weapon.
2. Chemical terrorism incidents are the same as biologic terrorism incidents.
3. It is impossible to plan for events of this type.
4. Intensive care unit planning is the same as emergency planning in other areas of the hospital.

CBRN, chemical, biologic, radiologic, or nuclear.

To plan appropriately for terrorist incidents, a local risk assessment must be made. Incidents involving CBRN weapons may be classified appropriately as a “low-frequency/high-consequence event.” Planning for a low-frequency/high-consequence event is more successful when these contingencies are built into the framework of existing emergency plans for more common events. CBRN medical planning focuses on the similarities of patient management to the typical management of patients in intensive care units (ICUs). Several fallacies pervade planning for CBRN events. These fallacies significantly impede appropriate ICU planning. Appropriate medical planning requires an understanding of the challenges posed by the following principles.

1. Civilian medical response is not the same as military medical response.

In 1975, the United States ratified the Biological Warfare Convention, which bans the development, production, stockpiling, acquisition, and retention of biologic agents and toxins. However, during the mid-twentieth century, the United States pursued a defensive and an offensive military chemical and biologic weapons program. During this time, potentially effective medical response measures to chemical and biologic agents were developed. Although most of the experience and scientific data concerning medical management of CBRN incidents have been conducted by or under the sponsorship of the US military, the goals and use of a CBRN weapon by a terrorist are fundamentally different from the military use of these weapons. The civilian population is a more heterogeneous population, chronologically and medically, than a military force. Additional planning needs are introduced by the unknown time and location of a terrorist use of a CBRN weapon coupled with the lack of psychological preparation of the civilian population. A large amount of military medical response is predicated on minimally affecting the readiness of the military force and rapidly returning to battle as many exposed soldiers as medically possible. These concerns generally are not appropriate in the civilian population. Military doctrine refers to

Table 1 Differences between biologic and chemical agents

Biologic agents	Chemical agents
Naturally exist	Man-made
Production difficult (scientific)	Production difficult (industrial)
None volatile	Many volatile
Among most toxic agents known	Less toxic than many biologics
Infectious agents reproduce	Do not reproduce
Cannot penetrate intact skin (most)	Can penetrate intact skin
Odorless and tasteless	Odor or taste or both when exposed (most)
Effects require incubation (days)	Effects immediate
Aerosol delivery (HEPA filters protect)	Aerosol/mist/droplet delivery (self-contained breathing apparatus and vapor-tight ensembles protect)

HEPA high-efficiency particulate air

the concept of *acceptable losses*; terrorist use of a CBRN weapon produces *unavoidable morbidity and mortality* in the civilian population. From these differences, it can be seen that despite basing medical care on the data developed by the military, medical care of civilian victims of a terrorist use of a CBRN weapon requires unique planning efforts and perhaps different treatment regimens.

Differences Between Military Use and Civilian Use of Chemical, Biologic, Radiologic, or Nuclear Weapons

Goals

Military use – efficiency degradation of opponent, denial of tactical or strategic objectives, demoralization of enemy

Terrorist use – infliction of terror or death or both, media attention to cause

Other Differences

Age and medical heterogeneity of a civilian population

Physical and psychological preparation of potential victim

Known location and time (war zone) versus use at a nonmilitary location without warning

Acceptable versus unavoidable losses

2. Chemical incidents are not the same as biologic incidents.

A common pitfall equates the planning needs and management principles for these two classes of agents. Several fundamental differences exist between chemical and biologic agents (Table 1). These differences alter the latency period and the presenting signs and symptoms of victims in events involving these agents.

Chemical agents refer to man-made chemicals designed to kill or incapacitate. Several classes of common industrial chemicals produce intoxications similar to the chemical threat agents, and patient management is similar to the management of victims exposed to these industrial chemicals. Emergency medical response and hazardous material response teams are important to the management of a chemical incident.

Biologic agents refer to living organisms or their biologic products that are intended to kill or incapacitate. A successful covert use of a weapon of this type is likely to manifest as an “unusual outbreak of an unusual disease.” This outbreak is likely to be recognized initially by an astute clinician or inferred via the public health and poison control reporting infrastructures. Use of biologic weapons heavily impacts public health resources and not directly emergency response/hazardous materials teams. Although the differentiation between a natural and man-made outbreak of disease may be difficult in the early stages of the incident, the ICU management of the patients is similar.

3. It is possible to plan for a terrorist use of a CBRN weapon.

It appears daunting to plan for a terrorist attack that may result in hundreds of victims requiring intensive care. It is possible to construct extreme scenarios that can overwhelm any response plan. However, a response plan that builds on existing daily capacity, established emergency plans, and emergency procedures to respond effectively to an incident can be developed. As a general rule, it is not a prudent use of medical resources to provide for a standby capability to manage a major CBRN

incident in most locations. It is the unusual hospital system in today's medical environment that can manage even a minor CBRN incident without relying on a regional or statewide "mutual aid" and patient disbursement capability. As was seen in the critical care of repatriated Ebola infected health care workers in 2015, small numbers of victims may be better served by transport to specialized centers for intensive care rather than receiving care in inexperienced hospitals. Certain high-risk potential targets, identified through a locally based risk assessment, may require a more extensive commitment of personnel and resources. The capabilities to provide intensive care, although scalable to a certain degree, are fixed by equipment and personnel availability. When these capabilities are exceeded by the magnitude of an incident, some combination of triage and regional/national patient transfer assistance is required. It still is possible to provide for the basic management principles as outlined subsequently as part of an intensive care plan for the medical management of victims of a terrorist use of a CBRN weapon, while additional resources are marshaled and patient disbursement occurs.

4. ICU planning is not the same as emergency planning in other areas of the hospital.

The needs and planning requirements of the ICU are different from those of other areas of the hospital. Intensive care is concerned with the *successful* use of a CBRN device. These events are significantly less frequent than the *threat* or false claim of use. In 1998–1999, more than 100 hoaxes claiming the release of anthrax occurred in cities throughout the United States. These incidents triggered a significant emergency response and resulted in a major improvement in various emergency response plans [4]. None of these hoaxes proved to involve a pathologic strain of *Bacillus anthracis*, and no victims required intensive care services. Emergency departments have to plan for decontamination of victims and triage of the nonexposed "worried well" from the truly exposed. Although these plans do affect intensive care planning, these concerns are less prominent in the ICU. ICUs are more concerned with the

procurement of pharmaceuticals, life-support equipment such as ventilators, maintenance of appropriate isolation, and staffing for a prolonged high-acuity patient population. Issues such as triage of scarce resources, provision of intensive care in nontraditional areas of the hospital, and forgoing or terminating futile therapy all assume significant planning needs for ICUs. There are key planning considerations in the development of a critical care response plan.

Key Components of Intensive Care Planning for Chemical, Biologic, Radiologic, or Nuclear Events

Provision of high-acuity-level staffing for prolonged periods

Procurement of pharmaceuticals, antidotes, antimicrobials, and equipment (e.g., ventilators)

Provision and proper use of appropriate personnel protective equipment

Indications for cohort nursing

Interface with hospital epidemiology and community public health

Disposal of large amounts of potentially biohazardous waste

Provision of critical care in nontraditional areas of the hospital

Austere critical care

Triage within the intensive care unit

Termination of futile therapy

Psychological support for caregivers

Intensive media focus and interest

Chemical Agents

The chemical threat agents of interest to ICUs include the organophosphate nerve agents, the cyanides, the vesicants, and industrial chemicals with predominantly respiratory effects, including phosgene and chlorine. Each of these chemical threat agents is clinically similar to more commonly encountered industrial chemical analogues and has similar management strategies (Table 2). The medical management of exposures to these

Table 2 Typical chemical threat agents

Threat agents	Military identification	Industrial chemical with similar nature
Nerve agents	Nerve agents	Organophosphate pesticides
Cyanide	Blood agents	Cyanides
Phosgene	Pulmonary (choking) agents	Chlorine
Vesicants	Blister agents	Acids and other corrosives

more common chemical agents is discussed in depth elsewhere in this book. Treatment recommendations for the terrorism related agents are largely composed of level III evidence [5]. This chapter focuses on the clinically significant differences in the medical management of these chemical threat agents versus their more commonly encountered industrial analogues.

Nerve Agents [6]

Nerve agents are among the most toxic of the chemical threat agents. Although they are referred to in the popular literature as *nerve gases*, all are liquid at room temperature. Although these agents were originally synthesized by the Germans during World War II in search of alternatives to the embargoed insecticide nicotine, their toxicity for mammalian nervous systems soon was appreciated. All of these agents (sometimes referred to as *G agents*) are organophosphate compounds. They differ from the more commonly encountered organophosphate pesticides in that the organic side chains are relatively short (ethyl and methyl moieties), and they differ in the electronegativity of the leaving group (usually containing fluorine or a cyano group). The volatility of these agents is slightly less than that of water. Volatility determines in part the onset of symptoms and the persistence of these agents in the environment. Another nerve agent, *O*-ethyl S-diisopropylaminomethyl methylphosphonothioate, usually referred to as VX, has a significantly lower volatility and vapor pressure, resulting in more persistence in the environment and on clothing. The nerve agents all are potent

irreversible inhibitors of acetylcholinesterase and butyrylcholinesterase in humans. Organophosphorus-containing pesticides may present similarly and are more widely available. The principles of ICU management are similar [5].

Although it is claimed that several “recipes” for the synthesis of nerve agents circulate on the “Dark” Internet, a review of these pages (accessed May 2015) show little more than reaction equations. The chemistry involved in the actual synthesis of these agents, together with knowledge of the appropriate reaction conditions, requires a significant background in synthetic chemistry. This background, the tight controls placed on the likely precursor materials, the reactivity of several of the intermediate products, the requirement for specialized reaction systems, and the need for containment of the resulting agent make the actual successful synthesis of nerve agents beyond all but the most sophisticated, well-funded terrorist groups. The production of sarin by the Aum Shinrikyo cult was estimated to cost \$30 million, involved 80 persons led by a Ph.D.-level scientist, and took at least 1 year to synthesize [7].

Clinical Effects

Exposure to nerve agents occurs usually via respiratory exposure to vapor, although skin exposure to a liquid agent may occur. The few case reports of industrial exposure to sarin vapor described significant miosis, rhinorrhea, mild respiratory distress, and wheezing in the victims [8]. These signs and symptoms also were observed in the victims of the Japan sarin incident. Victims who have continued exposure to the agent rapidly progress to unconsciousness, fine motor fasciculations, respiratory failure, and cardiovascular collapse. The timing and progression of symptoms depend on the dose delivered and the exposure circumstances. Clinical effects develop almost immediately after vapor exposure; they can be delayed several minutes if cutaneous exposure to a liquid agent occurs. Cutaneous exposure also may produce local sweating and muscle fasciculations at the site of contamination followed by nausea and vomiting.

Decontamination

Rapid scene decontamination of victims is required for any contact with a liquid nerve agent. Because of the toxicity of these agents and the time required for patients to arrive to the ICU, it is unlikely that any nerve agent remains on the skin when victims are admitted to the ICU. It is possible that an agent could be present in the hair, nail beds, and other areas where it has not been adsorbed. It is vital to confirm that adequate decontamination has occurred on arrival of the victim in the ICU. If any doubt about the adequacy of decontamination exists, careful skin cleansing with soap and water by ICU personnel clothed in personal protective equipment equivalent to universal (barrier/splash) precautions is required. Particular attention should be directed to the poorly adsorbed areas of the scalp and nail beds and other areas commonly missed in rapid scene or emergency department decontamination, including armpits, perineum, interdigital areas, and feet. Although nerve agents hydrolyze more rapidly in the presence of sodium hypochlorite, the potential toxicity of this agent on ocular tissue and mucous membranes makes the use of specialized decontamination solutions unnecessary in the ICU.

Stabilization

Stabilization of a patient exposed to a nerve agent is identical to the management of an organophosphate-exposed patient. Rapid decontamination, aggressive airway control, and respiratory support with assisted ventilation usually are accomplished in the prehospital area and emergency department. A significant difference between nerve agent and other organophosphate intoxications is the amount of atropine required to modulate the muscarinic symptoms. Atropine doses of 2–20 mg usually stabilize a victim exposed to a nerve agent [8]. This dose is significantly less than the hundreds of milligrams of atropine that may be required in some cases of pesticide intoxication [9]. The relatively lower doses of atropine required to reverse the muscarinic effects of nerve agents are not understood completely; it may be due in part to the potency of the agents compared

with industrial organophosphate agents. The clinical pharmacology of atropine use is described in detail in ► [Chap. 138, “Atropine.”](#)

Oxime Therapy

After decontamination, stabilization of the patient, and reversal of muscarinic symptoms with atropine, regeneration of the organophosphate-inhibited cholinesterase by oxime therapy is required (Level III evidence). When acetylcholinesterase is inactivated by a nerve agent, the enzyme can be reactivated either by spontaneous hydrolytic cleavage (a minor pathway with nerve agents) or by use of a nucleophilic oxime antidote. If neither occurs, the nerve agent–acetylcholinesterase complex undergoes dealkylation – a process referred to as *aging* – rendering the enzyme irreversibly inactivated. The speed of the aging process depends on the specific nerve agent. The aging half-lives range from a few minutes with soman (GD) [8] to 48 h with VX [10]. Sarin and tabun are intermediate, with aging half-lives of 3 h and 14 h, respectively [8]. Oxime therapy is most effective when administered within these half-lives. The implication is that successful oxime therapy likely requires prehospital or emergency department use of oximes to be most effective in cases of soman and sarin exposures. Some prehospital providers have access to Military Mark I kits, which contain 2 mg of atropine and 600 mg of pralidoxime chloride in autoinjectors for intramuscular injection. These providers are trained to administer the contents of three Military Mark I kits to victims exhibiting severe nerve agent poisoning.

Although other oximes have shown promise, pralidoxime chloride (Protopam Chloride) remains the only oxime approved for use in the United States. Ideally, it is infused intravenously at a dose of 15–25 mg/kg although larger doses may be required [5, 10]. Hypertensive effects of this drug are minimized by slow (over 30 min) infusion. Pralidoxime chloride is formulated in 600-mg autoinjectors for intramuscular use in the field (Military Mark I kit). These devices may be the only source of pralidoxime chloride available in the early hours after a significant incident because few hospitals that do not see

organophosphate-intoxicated patients on a regular basis stock sufficient supplies of pralidoxime chloride to treat more than one or two patients. The clinical pharmacology of oximes is covered in detail in ► [Chap. 158, “Oximes.”](#)

Care in the ICU

Patients who survive to be admitted to the ICU are at risk of developing seizures. Control of seizure activity induced by nerve agents is identical to control of other chemically induced seizures and may include benzodiazepines, barbiturates, and propofol. Diazepam is used widely by the military for seizure control; it is packaged in 10-mg autoinjectors for field intramuscular injection. There are no data to suggest, however, that diazepam is any more effective than the newer benzodiazepines [5].

Considerable anxiety and uncertainty may surround the need for isolation of critically ill victims and respiratory protection of the health care team. This anxiety is extrapolated in part from the uncertainty of the appropriate levels of protective equipment required for field health care workers and emergency department personnel. Assuming that emergency field decontamination with complete clothing removal, followed by additional skin decontamination in the emergency department, has occurred, the risk of significant contamination of the ICU is small. These agents do not off-gas from victims, so the standard barrier protective equipment available to the ICU should suffice to protect the health care team. The development of miosis or rhinorrhea in any members of the ICU team should trigger a reassessment of the adequacy of patient decontamination.

A more detailed review of these agents is found in ► [Chap. 135, “Nerve Agents.”](#)

Cyanide

The physiochemical properties of cyanide make successful mass casualty use of this chemical weapon by a terrorist difficult. Cyanides are not an effective weapon in outdoor use and are more likely to be encountered as an agent of product tampering, homicide, suicide, or assassination. Law enforcement personnel are familiar with the

use of cyanide salts in booby trap-type devices. Cyanide vapors are highly toxic in closed space encounters, prolonged vapor exposures, and ingestions. If vapor exposure is terminated immediately, recovery can be rapid, even without antidote use. The management of victims exposed to cyanide fumes is identical to the management of victims exposed industrially to cyanide and is covered in ► [Chap. 97, “Cyanide: Hydrogen Cyanide, Inorganic Cyanide Salts, and Nitriles.”](#)

Vesicants

Vesicants have the capability to produce severe cutaneous, ocular, and respiratory damage. Formation of large blisters after vesicant exposure is classic. During World War I, the vesicants resulted in the largest number of chemical casualties. Although considered a major chemical threat agent by the military and suspected of being used in regional conflicts in the Middle East, there has been little use of vesicants by terrorist groups. The principal agents in this class include mustard and lewisite. There is little evidence-based treatment recommendations (level III) available with most treatment recommendations being supportive care [5].

Mustard [11]

Chemistry and Pathophysiology. Sulfur mustard, bis-(2-chloroethyl) sulfide, distantly related to the alkylating chemotherapeutic agents, is a highly reactive electrophilic molecule that alkylates cellular DNA immediately on contact. Mechanisms involving cellular depletion of glutathione and free radical-induced cellular damage also have been proposed to explain the toxicity of mustard. Mustard exists as an oily liquid with a high vapor density and relatively low volatility. Exposure to mustard is likely through direct contact with the liquid agent or inhalation of vapor. The target organs of mustard exposure include the skin, eyes, and respiratory tract. Mustard does not produce immediate pain or symptoms, even though the cellular damage occurs within minutes after exposure. It is unique among the chemical agents in its lack of immediate symptoms of exposure. Cutaneous exposure to mustard produces

erythema approximately 4–8 h after exposure. The development of fluid-filled blisters occurs 2–18 h later. Ocular exposure initially produces a conjunctivitis that progresses in approximately 12 h to blepharospasm, corneal ulcerations, and occasionally panophthalmitis. Mustard produces dose-dependent inflammation and necrosis of the upper and lower respiratory tracts. This necrosis can result in pseudomembrane formation and obstruction of the tracheobronchial tree and secondary bacterial infection. Cough, hoarseness, and sinus tenderness may be present.

Decontamination and Treatment. Because of the speed by which mustard produces cellular damage, decontamination must occur within 1–2 min after contact to be effective. Thorough decontamination of the victim is required to protect the health care team from secondary contamination resulting from residual mustard liquid on skin or clothing. Treatment of mustard exposure is supportive and is similar to the management of other chemically induced burns. Respiratory support and bronchoscopy may be required for significant respiratory system involvement. Because of the alkylating effects of these agents, severe exposures may result in bone marrow suppression and require blood product or factor support. A detailed discussion of these agents is found in ► [Chap. 136, “Sulfur Mustard.”](#)

Lewisite

Lewisite, chlorovinyldichloroarsine, an arsenical vesicant, differs from mustard in its ability to produce immediate pain and stinging on contact. Lewisite produces clinical effects similar to those of mustard, although the onset of symptoms is much faster than with mustard. The development of immediate pain and irritation after contact with lewisite reduces the duration of ocular and respiratory exposures. Large exposures to lewisite may produce an increased capillary permeability syndrome with resultant shock. A specific antidote, British antilewisite, reduces the severity of injury when applied topically and ocularly. Preparations of British antilewisite for ocular and cutaneous use no longer are manufactured. Intramuscular British antilewisite may reduce systemic effects

for lewisite exposure, although clinical studies are lacking [5].

Chemicals with Predominantly Respiratory Effects

A wide variety of chemicals potentially available for terrorist use produce toxic vapors or gases [12]. These include the traditional chemical threat agents phosgene and chlorine, the nontraditional toxic by-products of conventional explosives, and the pyrolysis products of Teflon (perfluoroisobutylene). These chemical agents may produce toxicity via asphyxiation, direct corrosive effects on the respiratory system, or systemic toxicity. A key physiochemical property determining the location and extent of injury is the water solubility of the compound. Because the respiratory system is lined with a water-rich mucosa, chemicals with low water solubility are able to penetrate deeper into the lower respiratory system. These compounds also have poor warning properties because eye, nose, and upper airway irritation may be minimal or absent. Management of exposures to these chemicals follows standard medical approaches to industrial chemical exposures. Termination of exposure, scene decontamination, aggressive management of the airway, and respiratory support should be accomplished in the prehospital or emergency department setting. Noncardiogenic pulmonary edema or adult respiratory distress syndrome or both may supervene within 24 h. Management is identical to management of adult respiratory distress syndrome induced by other etiologies. There are little data (level III evidence) to support the prophylactic use of corticosteroids or inhaled sodium bicarbonate [5].

High-temperature pyrolysis of Teflon-containing substances produces perfluoroisobutylenes. Inhalation of this chemical produces a syndrome of fever and rapid development of pulmonary edema within 1–4 h (polymer fume fever). This edema may be worsened by significant exertion in the immediate postexposure period. Treatment is supportive. Inhalational

fevers are discussed in greater detail in ► [Chap. 100, “Irritant and Toxic Pulmonary Injuries.”](#)

Biologic Agents

Recognition

Biologic agents present more of a planning challenge to intensive care because the toxicity of these agents results in victims who potentially require prolonged critical care services and because of the geographic dispersion of victims that occurs during the incubation period. The delay from agent exposure to disease manifestation (due to the incubation period of most biologics) in the setting of worldwide rapid transportation systems makes it possible for a victim to be exposed to a biologic agent on one continent and manifest disease on another. The lack of immediate symptoms after exposure is a significant difference between chemical and biologic agents. This distinction is crucial because a successful covert use of a biologic agent is likely to manifest as an unusual outbreak of an unusual disease. The initial recognition of a terrorist event is likely to be made by an astute clinician recognizing an unusual outbreak of disease. The investigation of an outbreak of this type follows basic epidemiologic investigative principles, although there is tremendous pressure to accelerate the process. Most of the biologic threat agents exist naturally in the environment as zoonoses (e.g., anthrax and plague), represent rare intoxications (e.g., botulism), or typically present in geographically defined epizootic outbreaks (e.g., hemorrhagic fever viruses). Table 3 lists the biologic agents believed to present threat for terrorist use.

The requirements for successful use of a biologic agent arguably have been oversimplified in the popular press. Although much is written about the “ease” with which pathologic bacteria or viruses may be obtained, isolated, or genetically modified, the difficulty of producing large volumes of infective material and converting this material into a form and size suitable for delivery

Table 3 Critical biologic agents

Bacterial agents
<i>Bacillus anthracis</i> (anthrax)
<i>Yersinia pestis</i> (plague)
<i>Francisella tularensis</i> (tularemia)

to victims is underestimated. The Aum Shinrikyo cult apparently tried unsuccessfully to deliver biologic agents on multiple occasions without any evidence of successful infection [14]. In 1346 in the siege of Caffa, the corpses of plague victims were hurled into the city via catapult. This vignette illustrates the importance of the delivery system in the successful use of a biologic weapon!

Because many of the threat biologic infections present with similar nonspecific early symptoms and rapidly progress to a clinical picture indistinguishable from septic shock, it is likely that the initial victims would reach the ICU without a specific diagnosis being established. Because most of these threat infections are rare and because most physicians have never seen a case of plague, inhalational anthrax, or tularemia, they often are not included in the differential diagnosis of septic shock. Multiple cases of unexplained sepsis occurring in previously healthy young individuals should trigger the suspicion of a possible biologic outbreak. Further complicating the ability to reach a specific diagnosis rapidly is that many of the threat agents are not cultured in the microbiology laboratory because they resemble contaminants that routinely are discarded or not worked up further (*Bacillus*) or because the

appropriate medium is not plated routinely (tularemia and some *Salmonella* species). Because few case series of antimicrobial therapy of these uncommon diseases have been reported, and randomized trials of treatment regimens are sparse, antibiotic recommendations are largely anecdotal, derived from in vitro sensitivities of antimicrobials to the organism or extrapolated from animal models of disease (level III evidence).

Level of Isolation

Among the earliest decisions to be made in the ICU is the appropriate level of isolation of victims. This level is determined largely by the identification of the infecting organism. Early uncertainty as to the etiologic organism or fear and emotional reaction to the terrorist event often lead to maximal isolation – “just in case.” This irrational isolation may have adverse effects on personnel and resources. Most biologic threat agents either have no person-to-person transmission potential (anthrax) or have limited transmission potential (plague and hemorrhagic viruses). This limited potential for transmission should not be equated with minimal need for rigorous biocontainment protocols. As was seen with the Ebola outbreak in 2015, nosocomial transmission of virus occurred requiring the rapid development of detailed personal proactive equipment use protocols [15]. The major exception to limited transmission likely is smallpox, which may have significant secondary transmission potential. Cohort care and quarantine procedures may be appropriate if an outbreak of smallpox is suspected. Because skin adsorption of these organisms does not occur, barrier isolation (universal precautions) with HEPA level air filtration, respirators, and masks is sufficient to care for most patients in the emergency situation of an ICU with multiple victims. Additional patient decontamination beyond the emergency field decontamination is of a lower priority with biologic agent exposure compared with chemical agents. Because of static electrical charge, most crude biologic weapons

likely constructed by a terrorist group do not resuspend back into the air or produce secondary contamination of the health care team. A thorough shower or bed bath with antiseptic soap should suffice to decontaminate ICU patients adequately.

Chemoprophylaxis and Vaccination of the Health Care Team

The need for prophylactic antibiotic and vaccine administration for members of the health care team must be considered carefully. This need must be based on the transmission potential of the agent together with the ability of prophylactic antimicrobial therapy to prevent or attenuate disease. It is not reasonable to ask health care providers to care for patients at personal risk if an appropriate prophylactic regimen is available but not used. Fear and uncertainty regarding appropriate chemoprophylaxis can lead to inappropriate self-medication. Firm recommendations for prophylactic treatment of health care team members who have *not* been exposed in the terrorist incident have not been reported. Smallpox requires vaccination of treating personnel as soon as possible with vaccinia vaccine. If possible until arrival of the vaccine, victims should be cared for by previously vaccinated caregivers, who may be afforded at least partial immunity. Anthrax, because of lack of person-to-person transmission, probably requires no prophylaxis for caregivers. Cases of plague, particularly the pneumonic form, may be appropriate for health care team prophylaxis with a fluoroquinolone or doxycycline. Effective prophylactic antivirals currently do not exist for the viral hemorrhagic fevers.

Specific Agents

Anthrax

Anthrax (*B. anthracis*) is a gram-positive, nonmotile, spore-forming bacillus that has a worldwide distribution. Because of its ability to form long-lived, environmentally resistant spores, anthrax has significant potential as a biologic threat

agent. Anthrax naturally exists primarily as a zoonotic disease of cattle that become infected by ingestion of spores. Humans become infected by contact with infected animals or their contaminated products, such as wool, meat, or hides. Virulence factors in *B. anthracis* include an antiphagocytic capsule and two exotoxins, lethal and edema. Clinical disease in humans usually manifests as cutaneous anthrax, gastrointestinal anthrax, or inhalational anthrax. Inhalation of anthrax spores produces a hemorrhagic mediastinitis after an incubation period of 1–6 days. Although this incubation period is cited widely, an epidemiologic investigation of an anthrax outbreak in Sverdlovsk, Russia, in 1979, ascribed to an airborne release of weaponized anthrax, suggested that the incubation period may be as long as 45 days [16]. The mediastinitis rapidly progresses to septic shock. Meningitis may occur and manifest as seizures. When symptoms develop, even with aggressive supportive care, mortality of inhalational anthrax is estimated at 85%. The mortality of the inhalational anthrax series in the eastern United States in 2001–2002 was 45%.

Consensus recommendations (Level III evidence) for the medical management of a terrorist use of anthrax exist [17, 18]. Anthrax infection is treated with combination antimicrobial therapy often including high-dose penicillin [19]. Tetracycline, chloramphenicol, and erythromycin have also been suggested. In vitro activity has been shown against anthrax by the fluoroquinolones, gentamicin, vancomycin, and clindamycin – although there is not as much clinical experience with these drugs. Two antitoxins, raxibacumab and anthrax immune globulin, may also have utility in treatment [18]. In the early stages of an anthrax outbreak, the scarcity of antibiotics may require use of a variety of treatment regimens until the arrival of one of the predeployed national pharmaceutical caches. These caches, controlled by the US Public Health Service, are intended to supply a medical community rapidly with sufficient pharmaceuticals to treat the victims of a chemical or biologic incident.

Prophylactic antimicrobial treatment beginning within 24 h after exposure to anthrax aerosol confers protection against the development of disease in a primate model [20]. Ciprofloxacin, doxycycline, and penicillin were the antibiotics used in conjunction with active immunization with the human anthrax vaccine. This vaccine is produced from filtrates of an attenuated *B. anthracis* and contains predominantly protective antigen. Exposed victims not manifesting signs of illness need to receive prophylaxis with antibiotics as soon as possible after exposure and continue on oral antibiotics until vaccination with anthrax vaccine can be accomplished.

Plague

The causative agent of plague, *Yersinia pestis*, a gram-negative, nonsporulating, non-lactose-fermenting bacillus, that exists worldwide. Transmitted by fleas to rodents, *Y. pestis* normally produces enzootic infection in rodents. Intermittent epizootic outbreaks in rodents, particularly in rural areas, allow for human infection, usually from bites by infected fleas. Several virulence factors of *Y. pestis* have been identified and are coded for both chromosomally and on three plasmids. Because natural outbreaks of human disease sporadically occur, distinguishing a natural epizootic infection from a deliberate act may be difficult in the early stages of the outbreak.

Plague manifests in humans in the bubonic form, a suppurative lymphadenitis in the regional nodes draining the fleabite site; a primary septicemic form, similar in clinical presentation to other gram-negative septic states; and a primary pneumonic form, contracted from inhalation of an infectious *Y. pestis* aerosol. Septicemic plague also can develop into secondary pneumonic plague by involving the respiratory system. Plague often is suspected when a patient presents with the bubonic form, but less so when patients present with primary plague septicemia. A review of naturally occurring epizootic plague cases in New Mexico revealed that the correct diagnosis was suspected in 69% of bubonic patients but only 17% of the primary septicemic patients. Diagnosis of these

septicemic patients took 1 day longer (5 days), and the overall mortality was 33% [21]. Diagnosis of plague is made by Gram stain or direct fluorescent antibody stains of aspirates from the buboes and is confirmed by culture.

Because of the potential for person-to-person transmission of plague, plague patients with pneumonia and suspected primary pneumonic plague patients need strict isolation for the first 4 days of antibiotic therapy. Consensus treatment recommendations for plague include streptomycin and doxycycline [19]. It is unlikely that large amounts of these antibiotics would be available for treatment of multiple patients early in an outbreak. Gentamicin also has been used clinically. *In vitro* activity against *Y. pestis* has been shown by cefotaxime and levofloxacin [19]. A murine model of pneumonic plague showed the efficacy of ciprofloxacin and high-dose (20 mg/kg) gentamicin [23].

Tularemia

Tularemia, a zoonotic disease with worldwide distribution, is produced by *Francisella tularensis*, a gram-negative aerobic bacterium. Its principal animal reservoir is in several species of tick. Rabbits and other small mammals maintain the infection in nature. Humans become infected either via inhalation of an infectious aerosol or via breaks in the skin. Extremely low numbers of bacteria, on the order of 10–50 organisms, are sufficient to produce disease [24]. Most patients who cutaneously contract tularemia present with ulcers on the skin or mucus membranes, together with lymphadenopathy. Inhalational infection results in a nonspecific syndrome of fever, chills, headache, and myalgias. Pulse-temperature disassociation may be present, having been described as typhoidal tularemia. Diagnosis of tularemia is made by serologic evidence of infection or culture of the organism from fluids. Streptomycin is the current antibiotic of choice for treatment [19]; however, it is unlikely that a hospital would have sufficient stores of this antibiotic to treat multiple patients. Clinical experience supports the use of gentamicin. Ciprofloxacin and

doxycycline have afforded protection in animal challenge studies [25].

Botulism

The neurotoxins produced by clostridial organisms rank among the most potent toxins known. *Clostridium botulinum*, an anaerobic, spore-forming bacterium, elaborates seven neurotoxins that are capable of producing a flaccid descending paralysis with prominent bulbar symptoms. The bacterium has a worldwide distribution and usually produces intoxication via ingestion of contaminated food products. Direct multiplication of the agent in infants results in infant botulism [26]. Intravenous drug abusers can contract botulism via injection of contaminated illicit drugs [27]; in rare cases, direct contamination of open wounds produces wound botulism. These routes of exposure constitute the “typical” cases of botulism. In addition to these routes, direct inhalation of the purified toxin is a potential terrorist route of exposure.

Bulbar symptoms, including diplopia, ptosis, dysphagia, and dysarthria, are among the earliest manifestations of botulism. Muscle weakness progresses in a descending fashion until respiratory failure supervenes. The absence of convulsions can differentiate botulism from nerve agent exposure. Botulism differs from the other biologic agents discussed in the absence of fever and a nonspecific viral-like syndrome. Because of the small amount of botulinum toxin needed to produce disease from inhalation, it is unlikely that serologic examination of blood would yield the diagnosis. Enzyme-linked immunosorbent assay identification of the toxin from samples obtained from nasal mucosa identifies inhalational botulism in primate models.

Early administration of botulinum immune globulin can attenuate symptoms; however, it is less effective after the disease manifests. In the USA with the exception of Alaska and California, which control their own supplies of immune globulin, botulinum immune globulin is controlled by the Centers for Disease Control and Prevention (CDC) [18]. A toxoid exists for preexposure

prophylactic use. Botulism is discussed in greater detail in ► Chap. 132, “Botulism.”

Smallpox

Variola virus, the causative agent of smallpox, is a member of the Poxviridae family of double-stranded DNA viruses. Because of the absence of an animal reservoir, natural smallpox was eradicated worldwide in 1977. Currently, smallpox virus exists officially in only two locations – the CDC in the United States and laboratories in Russia. Clandestine stockpiles of variola virus may exist in several other countries. The high contagion rate of smallpox together with the virtual absence of immunity to the natural disease ranks smallpox among the most dangerous of the biologic threat agents.

Smallpox is infectious by aerosol and through contact with infectious lesions. Mortality in unvaccinated victims is approximately 30%. Immunity conferred by vaccinia vaccination wanes after approximately 10 years. Persons previously vaccinated would be expected to have an attenuated form of variola with an estimated mortality of 3%.

The lesions of variola resemble other vesicular exanthems, especially varicella (chickenpox). Because most clinicians practicing today have never seen a case of variola, the possibility exists of delay in recognizing the disease. Table 4 highlights some key differences distinguishing varicella and variola lesions. Consensus recommendations for management of terrorist use of smallpox have been published [18, 28].

Even a small suspicion of smallpox infection requires immediate strict isolation. The suspected diagnosis must be reported immediately by telephone to public health personnel because this

disease has international quarantine requirements. A single case of smallpox would strongly suggest that a bioterrorism event has occurred. Treatment of smallpox is largely supportive, although the antivirals tecovirimat and cidofovir are in late stage development [18].

Viral Hemorrhagic Fevers

Several RNA viruses from diverse families share the ability to induce an acute febrile illness in humans with profound increased vascular permeability and shock. These syndromes all have high morbidity and mortality. Most of these viruses have an animal host, although some (e.g., Ebola) have not had the animal reservoir conclusively identified. Table 5 lists the hemorrhagic viral agents considered to be threats.

The development of clinical illness varies with each agent and depends on the route of exposure, viral virulence factors, and host responses to infection. The onset of a viral prodrome, with fever, malaise, conjunctival injection, and myalgias, rapidly develops into shock with generalized bleeding from the mucous membranes. The degree of hemorrhagic manifestations is variable, being less in Lassa fever and more prominent in Ebola hemorrhagic fever. Diagnosis of a hemorrhagic fever is made initially on a clinical basis with confirmation by immunologic identification of antibodies to the virus. The patient’s travel history usually is a key part of the history to suggest the particular etiologic virus. This history is not present with a terrorist use of one of these agents. Although the virus usually can be isolated from the patient, the virulence of these agents requires special containment procedures, and viral culture

Table 4 Key features for distinguishing between variola and varicella

Feature	Variola (smallpox)	Varicella (chicken pox)
Incubation	7–17 days	14–21 days
Prodrome	Fever 2–4 days before rash	None
Pock aging	Synchronous	Asynchronous
Pock spread	Centrifugal	Centripetal
Pock location	Involves palms and soles	Seldom involves palms and soles
Infectivity	From exanthem until vesicles scab	1 day before exanthem until vesicles scab

Table 5 Threat of viral hemorrhagic viruses

Disease	Virus (family)	Natural distribution
Ebola hemorrhagic fever	<i>Filovirus</i>	Africa
Marburg hemorrhagic fever	<i>Filovirus</i>	Africa
Lassa fever	<i>Arenavirus</i>	Africa
Argentine hemorrhagic fever	<i>Arenavirus</i>	South America

attempts are carried out only in highly specialized and secured laboratories.

Treatment of hemorrhagic fevers is supportive; volume replacement, correction of reversible coagulation abnormalities, and blood product support are crucial. Case reports of critical care management of ebola have been published [29]. Ribavirin has been shown to have activity against Lassa fever [30] and hemorrhagic fever with renal syndromes produced by viruses in the Hantavirus genus [31]. A loading dose of 33 mg/kg, 16 mg/kg every 6 h for 4 days, and 8 mg/kg every 8 h for 3 additional days seems effective. Barrier precautions seem to be effective for naturally occurring outbreaks of these diseases. No vaccine exists for these viruses except for yellow fever vaccine although several vaccines and antiviral therapies are under active investigation for Ebola virus.

History of the Use of Nerve Agents

Nerve agents are organophosphate (OP) compounds, similar to OP pesticides, and are a group of potentially lethal chemical warfare agents (CWA). They are extremely potent inhibitors of the enzyme acetylcholinesterase (AChE), a key regulator of cholinergic neurotransmission. Early attempts in the synthesis of OP were made by Von Hofman, who developed methylphosphor chloride in 1873. Michaelis in 1903 introduced a compound with P – CN bond, which led to the synthesis of many OP compounds, including the nerve agent tabun. Lang and Von Kreuger synthesized compounds with P – F linkage in 1932. Schrader developed sarin and tabun in 1937; in 1944, Germans developed soman. British scientists developed VX in 1952 [1].

Exposure of nerve agents to humans was restricted to one prospective study with VX and sarin and to case reports of treatment of accidental exposure to sarin and soman [2]. The first reported use of nerve agents in a war occurred in February 1984 in Majnoon Island, by the Iraqi army against the Iranian troops. The nerve agent tabun was found in the environmental samples and in the postmortem examination of the patients who died soon after exposure. More than 300 patients died within 30 min of exposure in the field, and several thousands were poisoned by tabun [3]. Toxicologic analyses of the blood, urine, skin, and gastric juice of the chemical war gas victims revealed tabun and sulfur mustard [4]. Later in 1987 and 1988, particularly during the Halabjah massacre, another nerve agent (sarin) also was identified [5].

A presumed terrorist attack with sarin occurred in a residential area of the city of Matsumoto, Japan, on June 27, 1994. About 600 residents and rescue staff were poisoned; 58 were admitted to hospitals, and 7 died [6]. On March 20, 1995, terrorists released sarin at several points in the Tokyo subway, killing 11 and poisoning more than 5500 people [7]. United Nation has confirmed that sarin was used on 21 August 2013 in Ghouta area of Damascus, Syria [8].

Relevant Chemistry

Nerve agents are divided into two groups of G (comes from Germany) and V (abbreviated from Victory, as the British who first synthesized after the World War I victory, named it) agents. The G agents (except for tabun, which is a cyanide derivative) are fluorinated OP compounds. The V agents are sulfur-containing OP compounds. The principal G agents, GA, GB, and GD, have the common names of tabun, sarin, and soman, respectively. The other G agents and V agents do not have common names. The oldest and most common V agent is called VX. The names and chemical structures of all nerve agents are summarized in Table 1.

Although both G and V agents are commonly called nerve gases, they exist under temperate conditions as clear, colorless, viscous liquids with high boiling points. They become aerosolized when dispersed by spraying or by an explosive blast from a shell or bomb. The G agents are only moderately volatile (vapor pressure of <2 mmHg at 20 °C), but owing to their great

Table 1 Names and chemical structures of nerve agents

Short name	Common name	Synonym	Chemical name
GA	Tabun	mLe-100	Ethyl dimethylphosphoramidocyanidate
GB	Sarin	Zarin	Isopropyl methylphosphonofluoridate
GD	Soman	Zoman	Pinacolyl methylfluorophosphonate
GE	–	–	Isopropyl ethylphosphonofluoridate
GF	–	–	Cyclohexyl Methylphosphonofluoridate
VX	–	–	O-Ethyl-S-(2-diisopropylaminoethyl)methylphosphonothioate
VE	–	–	O-Ethyl-S-(2-diethylaminoethyl)ethylphosphonothioate
VG	–	–	O,O-Diethyl-S-(2-diethylaminoethyl)phosphonothioate
VM	–	–	O-Ethyl-S-(2-diethylaminoethyl)methylphosphonothioate

toxicity, the vapors pose a significant inhalational hazard. Vapor pressure of the G agents is sufficiently high for the vapor to be disseminated rapidly. GB (sarin) is mainly a vapor hazard. VX is less volatile and is normally a liquid contact hazard. Delivery systems of nerve agents include bombs, missiles, cluster spray, and spray tanks. G agents spread rapidly on surfaces such as skin and in the lungs. They are dispersed within hours and are described as *nonpersistent agents*, whereas VX spreads slowly and remains in the place for weeks or longer after exposure and is thus called a *persistent nerve agent*. Clothing releases G agents for about 30 min after contact with vapor [9]. If G agents are released into the air, they are degraded rapidly by reaction with photochemically produced hydroxyl radicals and have an estimated half-life of 10 h.

Nerve agents are four to six times more dense than air. As a result, they tend to remain close to the ground and pose a risk particularly to people in low areas and below-ground shelters. The nerve agents are soluble in water, organic solvents, and fat. After contact with water, they are hydrolyzed to products that are less toxic than the parent compounds [10].

Pathophysiology

Mechanism of Action

The well-known mechanism of action of OP compounds is the inhibition of cholinesterases. Two types of cholinesterase are involved:

1. AChE is a specific enzyme useful for the diagnosis of OP poisoning; it also is called *true cholinesterase*. It usually is estimated in red blood cells and called *RBC AChE* or *erythrocyte AChE*.
2. Butyrylcholinesterase (BChE) is less specific but more sensitive than AChE for the diagnosis of OP poisoning. It also is called *pseudocholinesterase*. BChE is usually estimated in plasma and is so-called *plasma cholinesterase*.

The reaction between OP compounds and AChE occurs in three steps, as shown in Fig. 1 [10]. The toxic manifestations and lethality after nerve agent exposure seem to follow the irreversible phosphorylation of the serine-containing active site of AChE. BChE also is inhibited. People with BChE genetic variation deficiencies may

Fig. 1 Three-step reaction mechanism for the inactivation of acetylcholinesterase (AChE) by an organophosphate compound. Step 1 depicts the formation of a reversible complex between a serine residue in the AChE active site and the organophosphate. Step 2 shows the elimination of the organophosphate leaving group (X^-). In step 3, the aging of the AChE is completed, forming a phosphorylated AChE

be at risk. The clinically most important variant is atypical (D70G) BChE because people with this variation have 2 h of apnea after receiving a dose of succinylcholine that is intended to paralyze muscle for 3–5 min [11].

Different aging mechanisms are involved. Tabun and butyl-tabun seem to be accommodated similarly in the active center, as suggested by molecular modeling via kinetic studies of phosphorylation and aging with a series of HuAChE mutants (E202Q, F338A, F295A, F297A, and F295L/F297V) [12]. A variety of proteolytic enzymes (e.g., chymotrypsin, trypsin) also may be inhibited by OP nerve agents. Soman and sarin are detoxified in part via a two-step pathway involving bioactivation of the parent compound by the cytochrome P-450 system, then hydrolysis of the resulting oxygenating metabolite (oxon) by serum and liver paraoxxygenase (PON1). Serum PON1 has been shown to be polymorphic in humans [13].

Biochemical Changes

Acetylcholine accumulation is involved in the calcium flux into skeletal muscle fibers during OP poisoning [14]. Bright and coworkers (1990) [15] reported a histochemical demonstration of sarin-induced calcium influx in mouse diaphragm, which may be linked with OP-induced myopathy. Sarin may induce myonecrosis. Significant increase in alkaline phosphatase and creatine phosphokinase activity and minor changes in coagulation parameters (prothrombin time, activated partial

thromboplastin time, fibrinogen) were observed after soman poisoning in rabbits [16]. Significant increases in creatine phosphokinase, lactate dehydrogenase, alanine aminotransferase, aspartate aminotransferase, and serum potassium, associated with damage to striated muscle and metabolic acidosis, occurred 2 days after GF poisoning in 20 male rhesus monkeys [17].

Toxicity

The vapor pressure of the three G agents (GA, GB, and GD) makes them significant inhalational hazards, especially at warmer temperatures or when droplets are created by explosion or spray. Based on information from animal studies, the lethal inhaled dose of G agents in humans may be about 1 mg. The G agents also represent a skin contact hazard, particularly when evaporation is minimized and contact is prolonged by contamination of clothing. The percutaneous absorption of G agents is much less rapid and complete, however, than the inhalational form [9].

VX does not pose a major inhalational hazard under usual circumstances, but it is well absorbed through the skin [9]. The relative lethality as determined in animal studies is VX > soman > sarin > tabun [18]. Acute toxic values of nerve agents in humans are summarized in Table 2.

The acute toxicity of nerve agents is due primarily to irreversible inactivation of AChE leading to an accumulation of toxic levels of acetylcholine. Similar to other OP compounds, these agents act by

Table 2 Summary of available acute toxic values of nerve agents in humans

Term	Unit	Route	Tabun	Sarin	Soman	VX
LD ₅₀	mg/kg	PC		28

Based on Dunn and Sidell [9]; Sidell and Borak [10]

binding to a serine residue at the active site of a cholinesterase molecule, forming a phosphorylated protein that is inactive and incapable of breaking down acetylcholine. The stable phosphoryl enzyme complex can undergo one of two possible processes:

a. Reactivation: The use of an appropriate nucleophile can trigger hydrolysis of the phosphoryl enzyme which can lead to reactivation of the enzyme [19].

b. Aging: Cleavage of the PO-C bond of the phosphorylated protein and the subsequent release of an alkyl carbenium ion is a process that is referred to as aging. In this case, the enzyme can no longer be reactivated even with the aid of a nucleophile.

In addition to the classical definition of aging of AChE described above, other definitions have also been proposed. One example involves the breakage of the P-N bond (as opposed to the PO-C bond) [12].

The reactivation of the aged AChE in many cases is not feasible, and the inhibition of the enzyme is considered irreversible. This is in part due to the negative charge at the active site of the enzyme, which makes any nucleophilic attack difficult [20].

The accumulation of toxic levels of acetylcholine at the synapse initially stimulates, then paralyzes cholinergic synaptic transmission (Fig. 2). Cholinergic synapses are found in the central nervous system, at the termination of somatic nerves, in the ganglionic synapses of autonomic nerves, and at the parasynaptic nerve endings, such as those in the sweat glands [10].

The rate of aging varies greatly among the nerve agents. The half-time of aging is within minutes after soman exposure, about 5 h after sarin exposure, and more than 40 h after exposure to tabun and VX [18].

OP compounds also bind to other esterases and cholinergic receptors. Inactivation of neurotoxin esterase by some OP pesticides can lead to delayed peripheral neuropathic effects known as organophosphate-induced delayed neuropathy (OPIDN). At many times the median lethal dose (LD_{50}), the nerve agents inhibit neurotoxin esterase to some extent, although the activity of VX is much less than that of G agents [21]. Possible involvement of neurotrophic factor (growth-related enzyme ornithine decarboxylase) during early stages of

OPIDN, particularly after diisopropylfluorophosphate, has been reported [22]. Nerve agents also bind quickly to cardiac muscarinic (M_2) receptors at higher than physiologic concentrations, but whether this contributes to cardiac toxicity is unknown [23]. They also interact with the nicotinic acetylcholine receptor-ion channel complexes, but only at tissue concentrations of 10–100 times greater than the concentrations fully inhibiting AChE. Sarin, soman, and tabun are partial agonists of these channel complexes, whereas VX acts as an antagonist [24]. There also is evidence that nerve agents affect noncholinergic mechanisms in the central nervous system at a dose approaching LD_{50} [25]. Antagonistic effects of γ -aminobutyric acid (GABA)-ergic systems may explain convulsive activity after OP poisoning. Effects of soman and tabun on the uptake and release of GABA and glutamate in the synaptosomes of guinea pig cerebral cortex did not support the previous belief that nerve agents cause convulsions by affecting the uptake or release of GABA or glutamine. Indirect evidence that soman and tabun inhibit catabolism of GABA and glutamine was obtained, however [26].

Acute exposure to tabun, sarin, or soman increases brain levels of cyclic adenosine monophosphate and decreases cyclic guanosine monophosphate as a result of stimulation of adenylyl cyclase and phosphodiesterase systems [6, 27]. VX at concentration of 10 μ M produced a significant reduction in cell metabolism within 2 min as measured by changes in the acidification rate of medium culture after 4 h of exposure. Two alkali degradation products of VX produced no cytotoxicity [28].

Toxicokinetics

As the OP nerve agents are lipophilic, they are absorbed rapidly following inhalation or ingestion. Dermal absorption is slow, but severe poisoning may still ensue if exposure is prolonged. Following absorption, OP nerve agents accumulate in fat, liver, kidneys, and salivary glands. Shih and co-workers (1994) studied toxicokinetics of GB, GD, and GF in rats. They had collected urine, blood, and lung tissue from rats dosed

Fig. 2 Cholinergic signaling in neurons and bronchial epithelial cells. **(a)** In neurons, choline for ACh synthesis is transported by the choline high-affinity transporter (CHT1). ACh is then synthesized by the action of choline acetyltransferase (ChAT) and packaged into synaptic vesicles by the action of the vesicular acetylcholine transporter (VACHT) and CHT1. ACh is then secreted by the complex processes that control synaptic release. Released ACh then interacts with postsynaptic nAChR and mAChR as well as presynaptic receptors. Signaling is terminated by acetylcholinesterase (AChE) and butyrylcholinesterase (BChE). Key signal transduction events lead to the generation of action potentials, opening of membrane and internal ion channels, muscle contraction, and kinase activation. **(b)** In bronchial epithelial cells (BEC), though CHT1 is present, CHT1 does not appear necessary for choline transport for

ACh synthesis. In BEC, as for neurons, ChAT is utilized for ACh synthesis, though since there are multiple isoforms of ChAT, different splicing products may be utilized in different cell types. Since CHT1 is not required, and BEC do not have synaptic vesicles, the role of VACHT and CHT1 in ACh secretion is unknown, though both are expressed in BEC. ACh released by BEC is inactivated by the same cholinesterases as expressed in neurons. A key difference is that released ACh is not limited just to synaptic communication, but can also signal multiple neighboring cells as a paracrine factor or more distal cells as a hormone (From *Muscarinic Receptors: Handbook of Experimental Pharmacology* 208, 2012. Fryer AD, Christopoulos A, and Nathanson NM, eds, Springer, with permission)

subcutaneously at $75 \mu\text{g kg}^{-1}$. Urinary excretion of the metabolite was the major elimination route for these three nerve agents. The major differences between them were primarily the extent and rate of excretion. Alkylmethylphosphonic acid is the single major metabolite formed and excreted in urine by a nonsaturable mechanism. Nearly total recoveries of the given doses for GB and GF in metabolite form were obtained from the urine. The terminal elimination half-lives in urine were 3.7 ± 0.1 and 9.9 ± 0.8 h for GB and GF, respectively. GD metabolite showed a biphasic elimination curve with terminal half-lives of 18.5 ± 2.7 and 3.6 ± 2.2 h. GD was excreted at a slower rate with a recovery of only 62%. Lung was the major organ of accumulation for this nerve agent. The toxic G agents were concentrated more in red blood cells than in plasma [29].

The metabolism of nerve agents results in the formation of inactive phosphonic acids, which are excreted via kidneys [30–32]. Experimental studies reveal that the elimination half-life of G agents was less than 1 h which is shorter than VX, which persists for several hours following intravenous administration and even longer after percutaneous exposure [33].

Oxidation and hydrolysis are principal metabolic inactivation pathways, which occur mainly by reaction with glutathione and also by glucuronidation and demethylation. Tabun causes the largest number of degradation products among the G agents. Detoxification of tabun takes place slowly, by di-isopropyl-fluorophosphatase, formerly termed tabunase. There are sparse toxicity data available for the subset of tabun degradation products. Ethyl-dimethylaminophosphoric acid is

the main product of tabun dimethylamine, which is also produced by hydrolysis of tabun. Dimethylamine causes human irritation in the respiratory tracts [34].

Isopropyl-methylphosphonic acid (IMPA) is a metabolite of sarin which subsequently hydrolyses to the high stable methylphosphonic acid (MPA) which mildly irritates rabbit skin and human skin and eyes [35].

In rats, 10 min after intravenous sarin, around 70% of the plasma was bound to large protein molecules similar to carboxylesterase [36]. The toxicity of sarin enhanced 6–8 times when the rats were pretreated with triorthocresyl phosphate, which is a weak anti-ChE OP with irreversible blocking carboxylesterase activity [37].

In a report of Little et al. (1986) who injected 80 µg/kg of sarin intravenously to mice, sarin concentration was at the highest in the kidney, liver, and plasma within one minute. Over the first minute, about half of the labeled sarin was associated with the major sarin metabolite; IMPA and the kidneys contained the highest concentration of sarin and its metabolites. Much lower hepatic concentrations after 24 h suggest a primary role of the kidneys in detoxification of sarin [38]. In another experiment of Little et al. (1988) with the same method, hypothalamus contained concentrations of both sarin and the metabolites 2–5 times greater than those in other brain areas. This finding suggests that the hypothalamus is more important with respect to central effects of nerve agents [39]. In 4 of 12 patients of Matsumoto with sarin exposure who underwent the study, the levels of IMPA and MPA correlated with clinical manifestations [40].

Pinacolyl methylphosphonic acid is the predominant hydrolytic product of soman [41].

A two-compartment model, with a biologic half-life of 1–1.5 min, described toxicokinetics of the four stereoisomers of soman in atropinized rats. The extremely toxic C(±) P(–) isomers could be followed in rat blood samples for more than 4 and 2 h at doses of 6 and 3 LD₅₀ (82 µg/kg). The toxicokinetics of P(–) isomers was described with a three-compartment model, with terminal half-lives of 40–64 min and 16–22 min at doses of 6 and 3 LD₅₀, respectively [41].

Clinical Presentation and Complications

The nerve agents cause toxic effects mainly by interfering with cholinergic synaptic function. This effect occurs at cholinergic neuroeffector functions (muscarinic effects), at the skeletal myoneural junctions and autonomic ganglia (nicotinic effects), and in the central nervous system. The signs and symptoms of nerve agent poisoning are classified according to whether they are due to overstimulation of muscarinic, nicotinic, or central nervous system receptors [42–53]. Nerve agents also cause long term and late complications [54–57].

Muscarinic effects of acetylcholine stimulation include miosis; blurred vision; eye pain; hypersecretion by salivary, sweat, lachrymal, and bronchial glands; bronchoconstriction; cough; cyanosis; pulmonary edema; nausea; vomiting; diarrhea; crampy abdominal pains; tenesmus; urinary and fecal incontinence; hypotension; and bradycardia (see ► Chap. 23, “Anticholinergic Syndrome”). Nicotinic effects include easy fatigue, weakness, muscle cramping, fasciculations, skeletal muscle twitching, convulsions, and flaccid paralysis. Nicotinic stimulation also can obscure muscarinic parasympathetic effects and produce mydriasis, tachycardia, and hypertension by stimulation of the adrenal medulla. Central nervous system effects include irritability; nervousness; giddiness; ataxia; fatigue; generalized weakness; depression of respiratory and circulatory centers with dyspnea, cyanosis, hypoventilation, and hypotension; lethargy; impairment of memory; confusion; convulsions; coma; and respiratory depression [6, 7, 10, 42, 51–53]. The main toxic effects of nerve agents at various sites in the body are summarized in Table 3.

Clinical Manifestations by Routes of Exposure

The effects of nerve agent exposure occur via inhalation, contact with skin and the eyes, and, rarely, ingestion. Most often, exposure is to vapor (inhalation) or liquid (percutaneous). After small-to-moderate doses, initial effects and their time of onset are determined by the route of exposure [47, 58–63]. In

contrast, large doses cause similar effects by all exposure routes, although the time of onset varies [10]. Gastrointestinal absorption rarely may occur through ingestion of contaminated food.

Inhalation

Exposure to low vapor concentrations may affect only the eyes, nose, and airways. Miosis, visual disturbances, rhinorrhea, and some degree of dyspnea develop within seconds to several minutes. The severity of dyspnea is dose dependent. Usually, these effects do not progress significantly when the patient is removed from contamination. After inhalation of high vapor concentrations, victims lose consciousness within 1 or 2 min, then have seizures, flaccid paralysis, and apnea. Other early effects of high vapor concentrations include miosis and copious secretions. Involuntary micturition and defecation also may occur. Unless medical assistance is immediate, victims may die within 30 min [43–46].

Skin Absorption

Percutaneous absorption of nerve agents varies according to the body site exposed and the

ambient temperature. VX was absorbed nearly eight times more rapidly from facial skin than it was from the volar forearm, and absorption increased markedly as surrounding temperature increased from 18 °C to 46 °C [27]. Initial local effects of liquid, which seldom are noticed, include muscular fasciculations and sweating at the contamination site. A large droplet also may cause gastrointestinal effects and complaints of malaise and weakness. Droplets containing near-lethal or lethal doses cause loss of consciousness, seizures, flaccid paralysis, and apnea. The onset of these effects is sudden, usually after a symptomatic interval of 10–30 min [10, 42].

Eyes

Miosis rapidly occurs after splash exposure or eye contact with vapor and later, if at all, after systemic poisoning. Unilateral miosis can occur if only one eye has been exposed. Miosis may be accompanied by deep aching eye pain, conjunctival irritation, and visual disturbances. Dim vision may be due to constricted pupils or inhalation of cholinergic fibers of the retina or central nervous system. The miotic pupil may improve vision (the pinhole effect),

Table 3 Main Toxic Effects and Clinical Manifestations of Nerve Agent Poisoning

Receptor	Target organ	Symptoms and signs
Muscarinic	Glands	
	Nasal mucosa	Rhinorrhea, nasal hyperemia
	Bronchial mucosa	Bronchorrhea
	Sweat	Sweating
	Lacrimal	Lacrimation
	Salivary	Salivation
	Smooth muscle	
	Iris	Miosis, blurred vision, decreased eye field
	Ciliary muscle	Failure of accommodation, eye pain
	Bronchial tree	Breathing difficulties, tightness of breath, bronchospasm (wheezing)
	Stomach	Nausea and vomiting
	Gut	Abdominal cramp, diarrhea
	Bladder	Frequency, involuntary micturition
	Heart	Bradycardia, hypotension
Nicotinic	Autonomic ganglia	Sympathetic effects, pallor, tachycardia, hypertension, mydriasis
	Skeletal muscle	Weakness, fasciculation, muscle twitching, convulsions, muscle paralysis, flaccid paralysis
Central	Central nervous system	Giddiness, anxiety, restlessness, headache, tremor, confusion, failure to concentrate, convulsions, respiratory depression, cyanosis, coma, apnea, death

although complaints of blurred vision are common [58]. Direct installation of diluted nerve agent into the eyes does not produce tissue damage [10].

Life-Threatening Complications

The most life-threatening complication is respiratory failure, which is due mainly to the effect of the nerve agents on the central nervous system [59, 60], although in one animal experiment with sarin, respiratory paralysis could be purely central, peripheral, or both, depending on the doses of sarin and atropine antidote employed [61]. Hypoxia also is a major problem in the nerve agent poisoning, as it may cause cerebral edema and convulsions and may induce histopathologic brain damage.

Cardiovascular complications sometimes are severe and life-threatening [47, 62] (See Figs. 3 and 4). The nerve agents tabun, sarin, soman, or VX at 5–10 times the LD₅₀ administered to guinea pigs induced circulatory arrest a few minutes after apnea in nontreated animals. Antidote treatment by atropine (10 mg/kg) and HI-6 or HLo-7 (30 mg/kg) 2 min later rapidly restored heart rate and arterial pressure and respiratory function to various degrees. The nerve agent injection caused marked sinus bradycardia and a subsequent complete atrioventricular block within 1–2 min. In guinea pigs with depressed respiratory function (<50%), intermittent ST-T wave alterations and second-degree atrioventricular heart block were observed [47]. Other reported electrocardiogram abnormalities in animal experiments and in humans exposed to nerve agents include torsades de pointes, atria fibrillation, idioventricular dysrhythmias, complete heart block, and ventricular fibrillation [6, 10, 47, 62]. Histopathologic changes compatible with toxic myocarditis were observed after sarin and soman in animal experiments [47], but myocarditis has not been reported in humans.

Intermediate Syndrome

The intermediate syndrome consists of marked weakness of the proximal skeletal musculature

(including the muscles of respiration) and cranial nerve palsies that occurs 1–4 days after acute poisoning. This syndrome, which was observed after certain OP pesticides poisoning [63], has not been reported yet after OP nerve agent poisoning. Intermediate syndrome may be a consequence of cholinergic overactivity at the neuromuscular junction, and a connection has been made between the intermediate syndrome and OP-induced myopathy or undertreatment. Myopathy has been observed histologically in experimental animals with the nerve agents tabun, soman, and sarin [14, 15]. It can be anticipated that the intermediate syndrome occurs in some cases of nerve agent poisoning (Fig. 5).

Delayed Neuropathy

Organophosphorus pesticides-induced delayed neuropathy is a symmetric sensorimotor axonopathy, tending to be most severe in long axons and occurring 7–14 days after exposure. In severe cases, it is an extremely disabling condition [64]. Inhibition of neuropathy target esterase seems to be necessary for OPIDN to develop. Other mechanisms may be involved, however. The trophic factor ornithine decarboxylase, a growth-related enzyme, was decreased in the spinal cord after the neuropathic agent diisopropyl-fluorophosphate [22]. Although OPIDN was not observed after nerve agent poisoning in experimental studies [65, 66] and in accidental nerve agent poisoning, a case of sensory polyneuropathy 7 months after sarin poisoning has been reported [67].

Temporary psychological effects, such as depression, fatigue, insomnia, irritability, nervousness, and impairment of memory, have been described after nerve agent exposure [57]. Electroencephalography in a person who was severely intoxicated with sarin showed marked slowing with bursts of high-voltage waves at a rate of five per second [42]. Epileptic-type changes of the electroencephalography were observed after sarin poisoning 11 months after exposure [6].

Fig. 3 Muscarinic signaling pathways in supraventricular (sinoatrial, atrial, and atrioventricular) myocytes. Acetylcholine (ACh) acts through M2 receptors to regulate ACh-activated K channels via a membrane-delimited mechanism involving direct activation by the $\beta\gamma$ subunits of the inhibitory G protein G_i . ACh also acts through M2 receptors to inhibit adenylyl cyclase (AC) activity via the α_i subunit of G_i , resulting in a decrease in cAMP production. This may occur in the absence or presence of agonists that stimulate cAMP production. Norepinephrine (NEPi) acts through β_1 -adrenergic receptors to stimulate cAMP

synthesis by directly activating all isoforms of adenylyl cyclase (AC) via the α_s subunit of the stimulatory G protein G_s . Changes in cAMP affect targets of protein kinase A (PKA)-dependent phosphorylation such as troponin I (TnI), phospholamban (PLN), and the L-type Ca^{2+} channel. Changes in cAMP also directly regulate pacemaker channels, which are permeable to both Na and K (From Muscarinic Receptors: Handbook of Experimental Pharmacology 208, 2012. Fryer AD, Christopoulos A, and Nathanson NM, eds, Springer, with permission)

Course and Prognosis

Victims with heavy exposure to nerve agents may die within a few minutes in the field. Persons with physical and chemical protection (pyridostigmine) who remain in a heavily contaminated area may become intoxicated after 30 min. A patient with moderate-to-severe intoxication who receives first aid and emergency medical treatment may survive for a few days to a few weeks, according to the severity of intoxication and type of treatment [44]. Death, however, is common.

Hypoxia, coma, convulsions, and respiratory failure are signs of a poor prognosis. Patients who remain severely hypoxic and cyanotic may develop cardiac arrhythmias and die quickly. Patients who develop apnea and do not receive assisted ventilation immediately may incur brain damage and either die or become vegetative. It is

unlikely that nerve agents possess the potential to give rise to OPIDN [45].

Soldiers who are caught unaware and who are exposed to large amounts of nerve agent before donning respirators and other protective clothing and who rapidly develop severe symptoms and signs are unlikely to survive. Soldiers who rapidly develop respiratory failure and who become incapable of self-administering their own autoinjector devices also have a poor prognosis, unless emergency medical treatment is provided rapidly [44]

Late Complications

The nerve agents are less likely to cause chronic diseases in comparison with sulfur mustard poisoning. However, hypoxic encephalopathy is reported as one of the most remarkable long-term neurologic toxic effects of the nerve agents [46]. Cardiomyopathy has been reported in soman

Fig. 4 Muscarinic signaling pathways in ventricular myocytes. Responses to M2 receptor activation are only observed in the presence of agonists that stimulate cAMP production. Norepinephrine (NEPi) acts through β₁-adrenergic receptors to stimulate cAMP synthesis by directly activating all isoforms of adenylyl cyclase (AC) via the α subunit (α_s) of the stimulatory G protein G_s. Acetylcholine (ACh) acts through M2 receptors to inhibit AC5/6 activity via the α subunit (α_i) of the

inhibitory G protein G_i. ACh acting through M2 receptors can also stimulate AC4/7 activity via the βγ subunits of G_i. Changes in cAMP affect targets of protein kinase A (PKA)-dependent phosphorylation such as troponin I (TnI), phospholamban (PLN), as well as L-type Ca²⁺, delayed rectifier K⁺, and CFTR Cl⁻ channels (From Muscarinic Receptors: Handbook of Experimental Pharmacology 208, 2012. Fryer AD, Christopoulos A, and Nathanson NM, eds, Springer, with permission)

and sarin intoxicated rats, which may be a cause of death; however, it is not reported in human cases yet [47]. Neurological assessment of 43 Iranian veterans 22–27 years post exposure revealed fatigue, paraesthesia, and headache as the most common symptoms and sensory nerve impairments as the most common observed clinical complication in the Iranian veterans with the nerve agents of tabun and sarin. Sensory nerve dysfunction is more prevalent than motor nerves, which predominantly was a distal sensory deficit [48].

Engel et al. (2004) reported fatigue, depression, and chronic pain as the common clinical presentations of “Gulf war syndrome” [49]. Electroencephalogram (EEG) studies on sarin patients showed significant slowing with bursts of high voltage waves at a rate of five per second on EEG, 11 months after the exposure [50, 51]. Asthenia, insomnia, fatigue, blurred vision, narrowing of the visual field, shoulder stiffness, slight fever, and asthenia were observed in patients who exposed to sarin 1 and 3 years after Tokyo subway explosion

[52]. Fullerton and co-authors (1990) on a review of article mentioned temporary psychological effects such as depression, insomnia, fatigue, nervousness, irritability, and memory impairment as long-term complication of exposure to NAs [53]. Page (2003) on a telephone survey of 4,022 sarin exposed patients 28 years post exposure reported poor concentration abilities and sleep disturbances in comparison with the controls [54]. Grauer et al. (2008) have studied late neuronal and behavioral deficit after sarin exposure in rats. The data showed long lasting impairment of brain function after single sarin exposure that developed with time [55]. There is no real evidence on carcinogenicity, mutagenicity, and teratogenicity of NAs [56, 57].

Diagnostic Considerations

Initial diagnosis of nerve agent poisoning can be made based on the exposure history (accidental, terrorism, chemical warfare attack) and clinical

Fig. 5 Management of nerve agent (NA) poisoning. *ABCs* airway, breathing, circulation, *ICU* intensive care unit

manifestations. In low-level exposure, the route of absorption may affect the clinical features, but in high-level exposure, severe intoxication occurs. Absorption is faster through inhalation than by skin contact. Estimation of AChE in erythrocytes is required to confirm the anticholinesterase diagnosis and to estimate the severity of intoxication. BChE estimation also may help, although it is not specific and may be low due to genetic variations [11].

Diagnostic certainty of nerve agent exposure requires toxicologic analyses of the environment,

blood sampling, or both. A biosensor, which is a potentiometer enzyme electrode for direct determination of OP nerve agent, has been developed [68].

A fiberoptic enzyme biosensor for the direct measurement of OP nerve agents has been developed. Concentrations of 2 μM can be measured in less than 2 min using the kinetic response. When stored in buffer at 4 $^{\circ}\text{C}$, the biosensor shows long-term stability [69]. A new method for retrospective detection of exposure to OP

nerve agents was applied to estimate serum sarin concentrations of the Matsumoto incident. The concentrations ranged from 0.2 to 4.1 ng/mL in serum [70]. Definitive evidence for the acute sarin poisoning of the Tokyo subway was obtained by detecting sarin-hydrolyzed products from erythrocytes of four victims in postmortem examinations [71].

Intravenous administration of atropine can be used as a diagnostic test for anticholinesterase poisoning, whereas oximes are used only for treatment [72]. Cholinesterase activity in postmortem blood as a screening test for OP nerve agent exposure was performed in 53 nonpreserved postmortem whole-blood specimens. There was a negligible loss of cholinesterase activity by the 7th day of the study. Cholinesterase activity could be applied as the screening test for anticholinesterase nerve agents [73].

Diagnosis of the delayed neurotoxin effects can be made by estimation of neuropathy target esterase, although it is unlikely to occur after nerve agent poisoning. Marked reduction of neurotrophic factor (ornithine decarboxylase) during the early stages of neurotoxicity also may be helpful when it is possible to perform it [22]. Measurement of nerve conduction velocity and electromyography may be useful for the diagnosis of the delayed neuropathy of OP nerve agents [74].

Toxicologic Analyses

Cholinesterases and Neuropathy Target Esterase Determination

Estimation of BChE in plasma is widely available and should be performed as soon as possible. Erythrocyte AChE is more specific, however, and has more quantitative value than BChE, although both enzymes usually are measured spectrophotometrically. Inhibition of greater than 50% activity of either enzyme confirms the diagnosis of an anticholinesterase poisoning. Reactivation of BChE is relatively more rapid, depending on the agent, severity of intoxication, and use of oximes, taking 1–4 weeks. In contrast, reactivation of AChE may take up to 3 months [6]. Neuropathy

target esterase shall also be estimated when there are clinical features of delayed neuropathy.

Nerve Agent Detection

Detection and estimation of nerve agents are easier in environmental samples than in blood and urine samples of patients. By using new technology, such as biosensors and fiberoptic bioenzyme, and new methods for detection and determination of nerve agents (e.g., sarin) in the serum and erythrocytes, identification and estimation of common nerve agents are possible [68–72, 75].

Oxime Estimation

Estimation of pralidoxime concentration in blood may be required, although it is not necessary for the routine management of the patient. To achieve a maximal therapeutic effect, however, a blood pralidoxime concentration of 4 mg/L should be reached. An obidoxime plasma level in the range of 10–20 μ M was estimated as appropriate. This was achieved in 34 severely OP-poisoned patients using regimen of 250 mg i.v. as bolus, followed by 750 mg/24 h and was maintained as long as reactivation was possible. The result confirmed using this definite regimen for adults [75].

Biochemical and Hematologic Analyses

Acid–base and electrolyte disturbances are common during severe nerve agent poisoning. Arterial blood gas analysis, estimation of serum electrolytes, liver and kidney function tests, amylase, creatine phosphokinase, and lactate dehydrogenase may be required for patient management. Hypokalemia and hyperglycemia are common and should be considered and corrected. Elevation of serum amylase may reveal acute pancreatitis. Transient elevation of liver enzymes, hematuria, leukocyturia, and proteinuria may be observed during nerve agent poisoning. Blood cell count and other hematologic tests may be performed as clinically indicated. Transient leukocytosis, particularly in polymorphonuclear neutrophils, may

be observed during severe nerve agent poisoning [45].

Other Investigations

Chest x-ray, electrocardiogram, electroencephalogram, electromyogram, nerve conduction velocity, spirometry, computed tomography, magnetic resonance imaging, and other investigations may be performed in nerve agent poisoning as clinically indicated [44].

Severity Grading of Intoxication

Severity grading of nerve agent poisoning can be done based on clinical manifestations, cholinesterase activity, and initial atropine dose required for atropinization.

Clinical Symptoms and Signs

Patients with OP nerve agent poisoning can be divided into four groups – mild, moderate, severe, and fatal – according to symptoms and signs of poisoning (Table 4).

Inhibition of Cholinesterases

Patients with nerve agent poisoning may be divided into three groups according to cholinesterase activities (Table 5).

Atropine Dose

Patients with OP nerve agent poisoning can be divided into three groups according to the initial atropine dose required for atropinization:

1. Mild: less than 2 mg
2. Moderate: 2–10 mg
3. Severe: greater than 10 mg [45]

Causes of Death

Death after nerve agent exposure is mainly due to respiratory failure resulting from depression of the respiratory center, paralysis of respiratory muscles, and obstruction caused by bronchospasm and bronchial secretions. Some animal studies suggest that lack of central drive is the major factor [59, 60]. Cardiomyopathy in soman-intoxicated and sarin-intoxicated rats has been reported [34] and may be a contributory cause of death.

Table 4 Symptoms and signs of organophosphate nerve agent poisoning

Grade	Symptoms	Signs
1 – Mild	Dizziness, anxiety, headache, nausea, weakness, tightness of breath	Failure of accommodation, rhinorrhea, sweating, salivation, coughing, lacrimation
2 – Moderate (worsening of the above features plus the following)	Restlessness, confusion, dyspnea, disorientation, abdominal pain, diarrhea	Pallor, miosis, failure of concentration, tachycardia, hypertension, muscle twitching, fasciculation, respiratory depression, bronchorrhea, loss of consciousness, bronchospasm
3 – Severe (worsening of the above features plus the following)	–	Convulsions, respiratory failure, pulmonary edema, flaccid paralysis, involuntary micturition/defecation, cyanosis, deep coma
4 – Fatal	–	Coma, convulsions, miosis, hypersecretions, apnea within a few minutes after exposure

Table 5 Cholinesterase Activities^a

Grade	Butyrylcholinesterase activity (%)	Acetylcholinesterase activity (%)
1 – Mild	40–50	50–90
2 – Moderate	10–40	10–50
3 – Severe	<10	<10

^aButyrylcholinesterase activity has less quantitative value than acetylcholinesterase activity

Status epilepticus occurred in animals after high doses of sarin, soman, or VX despite early treatment with atropine and pralidoxime. Prolonged seizures may cause anoxia and morphologic brain damage, which induces more morbidity and mortality [65, 66].

Treatment

Priorities

The first rule for managing chemical casualties is that the emergency responders must protect themselves from contamination, resulting from contact with casualties and the environment (Fig. 2). This can be done by wearing personal protective equipment or by thoroughly decontaminating the patient. At minimum, rescuers should wear a protective mask (or mask containing a charcoal filter for a self-contained breathing apparatus device, not a surgical or similar mask) and heavy rubber gloves (surgical gloves offer negligible protection) and avoid skin contact with victims until decontamination has been carried out [9, 76].

As soon as possible, victims should be removed from the contaminated place and decontamination must be initiated. Antidotes should be given at the onset of effects as appropriate (e.g., autoinjector containing atropine, obidoxime, and diazepam). For unconscious or severely intoxicated patients, priorities must follow the ABCs (airway, breathing, and circulation) of resuscitation. Oxygen administration and assisted ventilation should be undertaken as soon as possible in patients with respiratory distress. Because atropine reverses bronchoconstriction within minutes, one could hesitate to intubate a dyspneic, conscious patient who is likely to improve quickly. In a severely poisoned, unconscious, apneic patient, however, endotracheal intubation with assisted ventilation should be undertaken as quickly as possible.

Airway resistance may be high initially, causing some mechanical ventilators to malfunction, but this should return to normal after atropine administration. Frequent airway suctioning may be required for copious bronchial secretions.

Supplemental oxygen through an endotracheal tube with positive end-expiratory pressure is indicated for severely hypoxic patients. It is important to improve tissue oxygenation before atropine administration to minimize the risk of ventricular fibrillation. Advanced life support, including intravenous line placement, should be provided to all victims with evidence of respiratory compromise or other signs of severe exposure [10, 44].

Decontamination

Decontamination must be carried out at the earliest opportunity to limit skin absorption of the agent and prevent contamination of the rescuers. Thorough decontamination is essential before casualties enter an emergency department or other site of medical care to avoid contamination of staff and other patients.

Indications for ICU Admission in Nerve Agent Poisoning

1. Patients with severe nerve agent intoxication (see section on “[Severity Grading of Intoxication](#)”), particularly patients with respiratory failure who need mechanical ventilation, should be admitted to the intensive care unit.
2. Although intermediate syndrome has not clearly been reported in nerve agent poisoning, it may occur in some cases. Patients with moderate-to-severe intoxication even without assisted ventilation should be monitored, preferably in the intensive care unit, for treatment of possible sudden respiratory arrest due to muscle paralysis.

If the eyes have been exposed, they should be irrigated as soon as possible with running water or saline. Skin should be decontaminated by pouring on large amounts of a chlorine-liberated solution, such as 5% hypochlorite solution (household bleach), followed by copious water rinsing. If bleach is not available, the skin should be blotted gently (without rubbing) with generous amounts of alkaline soap and water followed by a water

rinse. Generous amounts of water alone can be used if nothing else is available. Water dilutes and physically washes away the nerve agents, but it does not hydrolyze them. Contaminated clothing and jewelry should be removed, and the underlying skin should be decontaminated thoroughly. Care should be taken to clear under the nails, the intertriginous areas, the axillae, the groin, and the hair [10, 45].

Experimental Antidotes

Fetal bovine serum AChE protected mice from multiple LD₅₀ doses of OP nerve agents [77]. BChE purified from human plasma also was effective in vitro and in vivo in mice and rats as a single prophylactic antidote against the lethal effects of nerve agents [78]. Addition of the oxime HI-6 to fetal bovine serum and AChE as a pretreatment drug amplified the efficacy of enzyme as a scavenger of nerve agents [79].

Recombinant DNA-derived AChEs showed a great improvement over wild-type AChEs as bioscavengers; they can be used to develop effective methods for the safe disposal and storage of OP nerve agents and are potential candidates for preexposure or postexposure treatment for OP toxicity [80]. By the use of cell immobilization technology, immobilized *Escherichia coli* with surface-expressed organophosphorus hydrolase was made to detoxify nerve agents [81]. By protein engineering techniques, one BChE mutant, G117H, was made to hydrolyze V and G agents, but it reacted much too slowly [82].

OP acid hydrolyses from two species of *Alteromonas* were cloned and sequenced to detoxify G agents, which was effective [83]. Cholinesterases that are covalently linked to a polyurethane matrix can be used effectively to remove nerve agents from and decontaminate surface biologic areas (skin or wounds) or other areas (clothing or medical equipments) or the environment. These cholinesterases could protect medical personnel from secondary contamination while attending chemical casualties and civilians exposed to highly toxic nerve agents [84].

A reactive skin decontamination lotion active against classic nerve agents and sulfur mustard was developed. The inactivation process was time and agent dependent and related to the ratio of OP to reactive skin decontamination lotion [85].

Pretreatment

In animal studies, pretreatment with reversible carbamate AChE inhibitors, such as pyridostigmine and physostigmine, enhances the efficacy of postexposure treatment of soman exposure or soman poisoning with atropine and pralidoxime chloride and permits survival at higher agent challenges [86]. His protection apparently is due to the fact that the more lethal nerve agents cannot attack AChE molecules bound by carbamates. Carbamylation of 20–40% of the erythrocyte AChE is associated with antidotal enhancement. Carbamate pretreatment does not reduce the effects of the agents and by themselves carbamates provide no benefit. Pretreatment is not effective against sarin and VX challenge and should not be considered a panacea for all nerve agents. It is of value for soman intoxication when agent challenge is followed by atropine and an oxime. Pretreatment is ineffective unless standard therapy is administered after the exposure.

Because physostigmine is toxic at the amounts required, pyridostigmine is the drug of choice for pretreatment (Grade III recommendation). The standard dosage is 30 mg orally every 8 h for impending nerve agent attack. Because pyridostigmine does not cross the blood–brain barrier, it causes no central nervous system toxicity of nerve agents. Carbamates must never be used after nerve agent exposure; in that setting, carbamate administration worsens, rather than protects from toxicity. Excessive doses cause many of the same toxic effects as do the nerve agents, and the recommended amounts caused annoying side effects in more than half of the population in a war zone. Eptastigmine treatment given intravenously protected mice better than physostigmine against soman exposure [87].

Pretreatment with a drug mixture (pyridostigmine, benactyzine, and trihexypenidyl) and antidotal treatment (HI-6 and benactyzine) were investigated in rats. This cholinergic-anticholinergic pretreatment in restoring respiratory and circulatory changes induced by soman is important [88].

Antidotes

Available antidotes (atropine, oximes) do not prevent respiratory failure or incapacitation [89]. Early aggressive medical therapy with antidotes and intensive care management are the keys, however, to prevention of morbidity and mortality associated with nerve agent poisoning.

Atropine

Atropine should be titrated with the goal of drying secretions and resolving bronchoconstriction and bradycardia [90]. There is no actual dose for atropine. The dose (2 mg) of atropine available in an autoinjector is not adequate for moderate-to-severe exposure to nerve agents. Atropine should be given intravenously in doses to produce mild-to-moderate atropinization (dryness of tongue, oropharyngeal and bronchial tree, tachycardia, mydriasis, and flushing) as soon as possible. At least the same amount as the initial atropinization dose should be infused in 500 mL of dextrose 5% constantly to sustain the atropinization and should be repeated as needed until the patient becomes asymptomatic. Continuous infusion of atropine effectively antagonizes the muscarinic effects and some of the central nervous system effects of nerve agent poisoning, but it has no effect on skeletal muscle weakness, seizures, unconsciousness, or respiratory failure [10, 44]. Large doses of atropine require higher concentrations of atropine preparation (e.g., 100 mg/10 mL made in Germany) or at least a vast amount of atropine (10–100 mg) in dextrose 5% solution, ready-made for intravenous infusion in severely nerve agent-intoxicated patients. Much lower atropine doses are required for nerve agents than for the severe OP pesticides poisoning.

Atropine should not be given intravenously to a hypoxic patient. (Grade III recommendation) Hypoxia occurs as a result of hypersecretion in the respiratory tracts. The secretion must be suctioned and oxygen given to overcome hypoxia before inducing atropinization. If the patient is hypotensive, atropine can be given through an endotracheal tube or intratracheally for more rapid absorption through the peribronchial vessels [45]. Aerosolized atropine has also been used and can be administered quickly by inhalation. Studies suggest that in addition to the local effects in the lungs, it is absorbed systemically [91].

Oximes

Oximes are mainly pyridinium compounds, which are divided into mono-pyridium and bis-pyridium oximes. Common oximes used in the treatment of nerve agent poisoning are presented in Table 6. Although oximes have been designed to reactivate the inhibited AChE, clinical experience has indicated that they are not always effective as reactivators, and at this time, none of them can be regarded as a broad-spectrum antidote [92]. The choice of oximes based on the data presently available also may depend on factors other than protection against lethality, such as cost and availability of the oxime and its side effects. Obidoxime (Toxogonin, Merck, Germany) is likely to cause more toxic effects (hepatitis after high doses) than pralidoxime and HI-6 [93]. HI-6 is the least toxic, but it is less stable in solution and is not commercially available in many parts of the world.

Pralidoxime, HI-6, and HGG-12 were used in dogs with soman and tabun poisoning. Pralidoxime (in conjunction with atropine and diazepam) showed the best protective effects in soman-poisoned dogs: The protective indices were 9 for pralidoxime, 6.3 for HI-6, and 3.5 for HGG-12. None of these agents was effective against tabun poisoning [94]. Efficacy of two other oximes, HLo-7 and pyrimidoxime (an analog of trimedoxime), in three times the LD₅₀ of sarin, soman, and GF and two times the LD₅₀ of tabun, was tested in mice. HLo-7 produced significant ($P < 0.05$) reactivation of

phosphorylated AChE, resulting in 47%, 38%, 27%, and 10% reactivation of sarin-inhibited, GF-inhibited, soman-inhibited, and tabun-inhibited mouse diaphragm AChE, respectively [95]. In a comprehensive study, the order of effectiveness against soman was HI-6, HLo-7, and pyrimidoxime. HLo-7 was extremely effective against tabun poisoning, whereas HI-6 and pyrimidoxime were of moderate value. Against GF, HI-6 and HLo-7 were extremely effective, obidoxime was moderately effective, and pralidoxime and pyrimidoxime were least effective [96]. In soman-intoxicated guinea pigs, HI-6 was therapeutically slightly more effective than HLo-7; HLo-7 was more effective than HI-6 against tabun intoxication [97].

Pharmacokinetics and effects of HI-6 in blood and brain of soman-intoxicated rats were studied. High doses of HI-6 can reach the brain in sufficient amounts to reactivate inhibited brain AChE. Signs of soman poisoning correlated positively to AChE inhibition and negatively to the concentration of inbound HI-6 in the brain, and soman intoxication significantly decreased uptake of HI-6 into the brain [98]. Reactivating potency of obidoxime, pralidoxime, HI-6, and HLo-7 in human erythrocyte AChE inhibited by soman, sarin, cyclosarin, and VX was studied in vitro. After soman, sarin, cyclosarin, and VX inhibition, the reactivating potency decreased in the following order: HLo-7 > HI-6 > obidoxime > pralidoxime [99]. Dose–response effects of atropine and HI-6 treatment in soman and tabun poisonings were studied in guinea pigs. Atropine had a large effect on the efficacy of HI-6 against both the nerve agents. They also were more effective

against soman than against tabun. Adjunctive treatment with diazepam enhanced the efficacy of HI-6 and atropine against soman [100]. The effects of common oximes in different nerve agent poisonings are summarized in Table 7.

Despite many oximes tested in animal experiments, the human experience in war or terrorism is limited to pralidoxime and obidoxime. Pralidoxime should be administered intravenously at a dose of 30 mg/kg initially over 30 min followed by a constant infusion of 8 mg/kg/h in dextrose 5%. Pralidoxime can be continued until full recovery or until atropine is required. Obidoxime was hepatotoxic at high recommended doses of 8 mg/kg initially and 3 mg/kg/h [5]. It may be given at a dose of not more than 500 mg initially and 750 mg/day. Liver function tests should be checked regularly during obidoxime therapy [45].

Diazepam

Behavioral efficacy of diazepam against nerve agents in rhesus monkeys was studied. The results showed that diazepam would be an excellent adjunct to traditional nerve agent therapy to facilitate behavioral recovery from nerve agent intoxication that might be encountered by medical military personnel on the battlefield [101]. Diazepam was the drug of choice for treatment of convulsions in nerve agents poisoning. (Grade III recommendation) The initial IV doses of 0.2–0.5 mg/kg in children and 5–10 mg in adults are recommended and may be repeated as required [102, 103].

Table 6 Common oximes used in the treatment of organophosphate nerve agent poisoning

Type of oxime	Generic name	Trade name	SUPPLIER/COUNTRY
Monopyridinium	Pralidoxime chloride (2-PAM)	Protopam	Ayerst/U.S./Canada
	Pralidoxime methylsulfate	Contrathion	SERB/France
	Pralidoxime methanesulfonate	P2S	U.K. government
Bispyridinium	Trimedoxime	TMB-4	
	Obidoxime	Toxogonin	Merck/Germany
	HI-6		
	HLo-7		
	HGG-12		

Table 7 Relative effects of oximes in organophosphate nerve agent poisoning

Oximes	GA (Sarin)	GB (Soman)	GD (Tabun)	GF	VX
Pralidoxime ^a	+++ ^b	++	+	+	+++
Pyrimidoxime	++	++	++	+	++
Obidoxime	++	+++	++	++	+++
HI-6	+++	++++	++	++++	+++
Hlo-7	++++	+++	++++	++++	++
HGG-12	NA	+++	+	NA	NA

^aproPAM, the tertiary amine analog of pralidoxime, penetrates the central nervous system more readily than pralidoxime. Consequently, proPAM would be expected to have greater beneficial effect in nerve agent poisoning than pralidoxime. This expectation has not in general been realized in experimental studies

^bKey: + = least effective; ++ = partially effective; +++ = moderately effective; ++++ = most effective
NA no data available

Diazepam has not only symptomatic anticonvulsant effect but also has more specific effect on cholinergic and GABAergic systems [104]. In severe cases of nerve agents poisoning, convulsion starts within seconds after losing consciousness. It may persist for several minutes until the victim becomes flaccid and apneic. In these cases, diazepam must be administered promptly [103].

Other anticonvulsant benzodiazepines, such as lorazepam and midazolam, are effective in stopping seizures in acute nerve agents poisoning [105–108]. (Grade III evidence) Midazolam, however, is more potent and more rapid than diazepam in treatment of seizure in nerve agents poisoning. It is thus recommended that midazolam replace diazepam as an urgent anticonvulsant treatment for the nerve agents-induced seizures. (Grade III recommendation) Barbiturates, phenytoin, and other anticonvulsants are not effective against seizure in nerve agents poisoning [102]. Fast acting barbiturates may be effective, but they have more CNS depressive than the benzodiazepines. Propofol may be used in OP-induced grand mal convulsions if the response to benzodiazepines was not satisfactory.

Gacyclidine

Gacyclidine is an antiglutaminergic compound that was studied as a complement to the available emergency therapy in OP poisoning. It was used in conjunction with atropine, pralidoxime, and diazepam in nerve agent poisoning in primates.

Gacyclidine prevents the mortality observed after early administration of the aforementioned classic emergency medications. (Grade III recommendation) Electroencephalogram recordings and clinical observations revealed that gacyclidine prevented soman-induced seizures and motor convulsions. It also markedly accelerated clinical recovery of soman-challenged primates. Gacyclidine prevented the neuropathology observed 3 weeks after soman exposure in animals [72]. In a case of severe nerve agent poisoning, gacyclidine represented a promising adjuvant therapy to the currently available polymedication to ensure optimal management of OP nerve agent poisoning in humans. Administration of gacyclidine at zero to 30 min after intoxication obtains optimal neuropathological protection [109].

Serum Alkalinization

Effects of sodium bicarbonate in OP pesticide poisoning were investigated in patients with moderate-to-severe intoxication. The goal of the investigation was to make an alkalization to reach and sustain the arterial blood pH between 7.45 and 7.55. Sodium bicarbonate was administered intravenously first to correct the metabolic acidosis, then as a constant infusion of 3–5 mg/kg/24 h until recovery or until atropine was required. Arterial blood gas analysis was performed at certain intervals to adjust the dosing [104, 105, 110, 111]. Esteratic portion of OP molecules are hydrolyzed in alkaline solution. Increasing one unit of

pH is accompanied by a 10-fold increase in OP nerve agent hydrolysis. The arterial pH of >7.50 makes the OP hydrolysis faster particularly the nerve agents and their metabolites that are weak acids [112, 113]. However, it should be administered carefully to avoid severe metabolic alkalosis. Administration of sodium bicarbonate helps to control the cardiotoxicity as judged by electrocardiogram [114] (Grade III evidence).

Magnesium Sulfate

IV administration of magnesium sulfate (4 g) in the first day after admission would decrease the hospitalization period and improve outcomes in patients with OP pesticides poisoning [115] (Grade II-3 evidence). Magnesium sulfate may reduce ACh release by blocking calcium channels [116]. It also reduces CNS overstimulation and reversed the neuroelectrophysiological defects from OP toxicity [117]. Additionally, magnesium sulfate has a bronchodilating effect in mild to severe asthmatic patients, and it may relieve bronchoconstriction in a dose-dependent manner [118]. Magnesium sulfate has recently been administered up to 16 g per day in OP pesticides poisoning in the Mashhad Toxicology center without serious side effects. However, applying magnesium sulfate in nerve agents poisoning needs further study.

Drug Interactions

Drugs reported as contraindicated in severe OP nerve agent poisoning are morphine and its derivatives, aminophylline, theophylline, and chlorpromazine. Morphine derivatives and chlorpromazine potentiate the drowsiness and coma. Aminophylline and theophylline may potentiate nicotinic syndrome. Drugs known to be hydrolyzed by the enzyme cholinesterase, such as suxamethonium (succinylcholine) and procaine, may have sustained effects [104].

Hemoperfusion

Effects of hemoperfusion through coated resin adsorbent synachrome E-5 were studied in five

anesthetized dogs after intoxication by two to six times the LD_{50} of VX and another four dogs after intoxication by two to three times the LD_{50} of sarin. Hemoperfusion therapy prevented the development of serious signs of intoxication, provided that the dose of both nerve agents was only two times the LD_{50} . It was concluded that hemoperfusion therapy in poisoning by the nerve agents sarin and VX is only partially successful [45].

Yokoyama et al. (1995) reported a 45-year-old woman who was severely intoxicated by sarin during Tokyo subway attack. She had been treated with atropine, 2-PAM, and respiratory support, while she received hemofiltration and hemoperfusion because of an insufficient response to treatment. When she regained consciousness, her pupils were dilated, cholinesterase activity had increased, and the patient survived [119].

Based on the first author's clinical experience, charcoal hemoperfusion may be used in severely intoxicated OP nerve agent patients, as the OPs and some of their metabolites are lipid-soluble organic compounds and can be absorbed by charcoal.

Intravenous Lipid Emulsion

Following the introduction of intravenous lipid emulsion in the treatment of human poisoning with lipophilic drugs [120], some authors express a hypothesis that the combination of intravenous lipid emulsions can apply to treating severe OP poisoning [121]. However, in a study on mice, it showed no significant effect of intravenous lipid emulsion against OP toxicity [122]. Whether lipid emulsion is beneficial is unknown. For a severely poisoned patient *in extremis*, it may be potentially beneficial.

Special Populations

Pediatric Patients

Children are more susceptible to OP nerve agents, as was seen during the Sardasht and Halabjah massacres. Mortality was higher in children than in adults. Children have lesser mass and more surface/volume ratio, more immature respiratory

system, and stratum corneum in the skin that facilitates dermal absorption. Besides, their neurotransmitter systems are immature that makes them more susceptible to an epileptogenic stimulus [105, 123].

Children are more sensitive to atropine and oximes [123]. Atropine administration should include the monitoring of vital signs, especially the pulse rate. Atropine must be adjusted based on heart rate between 140 and 160 beat/min [104, 123] (Grade III recommendation). Loading dose of pralidoxime in children should be at 25 mg/kg, which is infused over 15–30 min. It may continue by 10–20 mg/kg/h to achieve a plasma concentration of >4 mg/L [110, 124]. Half-life of pralidoxime in children is about twice that of adults [105].

The Program for Pediatric Preparedness of the National Center for Disaster Preparedness (NCDP) issued the first recommendations and treatment guidelines of pediatric disaster and terrorism awareness that is nationally accepted [125]. They recommended that the Mark 1 Auto-injector kits should be applied as first treatment of children with severe and critical nerve agents poisoning, especially when intravenous therapy is impossible or unavailable [123, 125]. In a recent experimental study, perinatal (postnatal day [PND] 7, 14 and 21) and adult (PND 70) rats were more susceptible than pubertal (PND 28 and 42) rats to the lethal effects associated with exposure to tabun, sarin, soman, and cyclosarin [126].

Pregnant Patients

OP nerve agents may cross the placenta and induce fetal intoxication. The fetus is more sensitive to OP nerve agents than the mother and more sensitive to atropine than the mother. Fetal intoxication may occur because OP nerve agents cross the placenta. The sensitivity of fetus to OP compounds and atropine is higher than their mothers [110]. Clinical experience on pregnant women in Sardasht and Halabjah who were exposed to sarin in the Iran-Iraq war discovered that mortality rate is higher in fetus than in the

mothers [104, 110]. Fetus of survived sarin poisoned pregnant women died within a few hours to a few days [104]. However, some pregnant women in the second and third trimesters of pregnancy intoxicated with commercial OP compounds have been successfully treated with atropine and 2-PAM and have delivered healthy newborns [127].

In pregnant women, administration of atropine should be with caution and at lower doses. Pralidoxime has potential teratogenic properties in animal studies, but has not been shown in humans and therefore should be used as clinically required [128]. Obstetric consultation may be necessary. Removing of a dead fetus should be performed immediately after improving the mother's clinical condition [110].

OP nerve agents may be excreted in the mother's milk. It would be advisable to stop breast feeding at least for a few days after exposure [44].

Elderly Patients

Elderly people also are more susceptible to OP nerve agents. Experience with sarin poisoning during the Iran-Iraq War in Sardasht and Halabjah revealed that morbidity and mortality were higher among the elderly. Multiple organ failure and complications were more common among the elderly than other adult age groups. Atropine, oxime, diazepam, and any other medication should be administered with caution. Depending on the age and clinical condition of the patient, critical care therapy should be initiated more rapidly. Elderly patients with OP nerve agent poisoning should be treated in the same priority group as children [104].

Rescue Staff and Hospital Personnel

Rescue staff and hospital personnel who are in contact with victims of OP nerve agent poisoning may become intoxicated due to secondary exposure. Among 59 rescuers and duty physicians, 8 had mild symptoms of sarin poisoning during the Matsumoto incident. All the rescue activities

had taken place without gas masks or decontamination procedures [108].

Secondary contamination of house staff that treated victims occurred during the sarin Tokyo subway incident. More than 20% of the house staff had symptoms, including ocular pain, headache, sore throat, dyspnea, nausea, dizziness, and nasal pain, but none were seriously affected [7]. Rescue staff and medical personnel in the field, during transportation, and in the hospital should protect themselves by proper gas masks, clothing, and thick gloves (not surgical gloves) [104].

Experience in War and Terrorism

Observations during the nerve gas attack of the Iraqi army against the Iranian troops in Majnoon Island revealed that the heavily exposed people died within 30 min after onset of coma, convulsions, hypersecretion, respiratory failure, and apnea. Although the medical facilities were not adequate in Majnoon Island, first-aid treatment and decontamination were performed. The victims with moderate-to-severe intoxication were transferred from the field hospital to medical centers in big cities for further management [45].

Recorded clinical manifestations include miosis, hypersecretions, hypotension, nausea, vomiting, abdominal cramps, diarrhea, loss of consciousness, respiratory depression, cyanosis, pulmonary edema, muscle twitching, and convulsions. Bradycardia and hypotension were observed more before treatment with atropine, whereas tachycardia, normal hypertension, mydriasis, and dryness of the tongue were recorded more after atropinization. Morbidity and mortality were higher in patients with severe respiratory distress and cyanosis who received large doses of atropine. It is vital to correct the severe hypoxemia and cyanosis before atropinization (see section on “[Treatment](#)”). Suctioning of naso-oropharyngeal and bronchial secretions (clear airway) and establishing adequate ventilation are the first priority. Intermediate

syndrome, which was described after OP pesticide poisoning [63], has not been observed with nerve agent poisoning [44, 45].

Sulfur mustard was the most common chemical warfare agent that was used by the Iraqi army. Mixed poisoning by tabun and sulfur mustard also was common. No exact quantitative records of the nerve agent exposure are available. It has been estimated that greater than 2000 patients with nerve agent (later on diagnosed as tabun) poisoning were treated in March 1984. Another massive nerve agent poisoning occurred during the Halabjah massacre. It also was diagnosed as sarin and mixed with sulfur mustard [68, 69].

Two main terrorist attacks with sarin occurred in Japan. The first one occurred on June 27, 1994, in Matsumoto with about 600 casualties and 7 deaths [6]. The second attack occurred on March 20, 1995, in the Tokyo subway system, killing 11 and injuring more than 5500 people [7]. Diagnosis of sarin on both occasions was made based on the chemical analysis of environmental samples similar to the diagnosis of tabun in Majnoon Island and sarin in Halabjah [4]. Confirmative tests of serum sarin concentrations of the Halabjah massacre, Matsumoto incident, and Tokyo subway incident [70] and detection of sarin hydrolysis products from erythrocytes of four victims of the Tokyo subway incident [71] were performed after the incidents.

Preparation for a chemical incident resulting from an accident, war, or terrorism is important in every community. Because the rescue staff and medical personnel usually are from different departments, coordination between them is required. Guidelines and treatment protocols [129] should be available to all personnel. It should be updated at certain intervals to use the results of new research. For instance, recent clinical studies have confirmed that midazolam is effective when given at the onset of seizures caused by nerve agents. However, midazolam and the other benzodiazepines are less effective at terminating seizures when given 30 min or later after OP nerve agents seizure onset, likely because of internalization or

downregulation of synapses, which can lead to diminished potency and seizure recurrence [130].

Teaching the staff and performing a simulation exercise at certain intervals is necessary. Public awareness through the mass media and even written instructions to the public are valuable and may prevent chaos during the chemical incident [45].

Key Points in the Diagnosis and Management of Nerve Agents

1. Although plasma cholinesterase activity is given as percentages or U/mL, it should be valued qualitatively rather than quantitatively. Because of genetic variation in plasma cholinesterase, lower activity may be observed in 5–20% of normal individuals. However, treatment is based on clinical manifestations.
2. Hypokalemia and metabolic acidosis, which occur during organophosphate nerve agent poisoning, should be corrected near to the upper limit of normal range.
3. Administration of atropine in single repeated doses is mentioned in other textbooks. Mild-to-moderate atropinization must be produced and sustained until the patient's recovery.
4. Mydriatic eye drops are not needed; mydriasis will be induced by intravenous atropine.
5. Aminophylline and theophylline should not be administered for bronchospasm during organophosphate nerve agent poisoning. Anticholinergic bronchodilators and β_2 -agonists (salbutamol, terbutaline) should be administered instead.
6. Although pulmonary edema is less common in organophosphate nerve agent poisoning than in pesticide organophosphate poisoning, it should be treated only by atropine and not by morphine, aminophylline, furosemide, or digoxin. Morphine and aminophylline are contraindicated in organophosphate poisoning; furosemide might induce dehydration and electrolyte imbalance.

Conclusion

Nerve agents are the deadliest CWA that need immediate interventions. The Iraqi army used nerve agents against the Iranian troops and innocent civilians in the cities of Sardasht and Halabjah during the 1980s. Sarin was also used in terrorist actions in Matsomoto and Tokyo Metro in 1994 and 1995, respectively. It was used in Syria civil war as well in August 2013. In spite of the chemical weapons convention and the active role of the Organization for Prohibition of Chemical Weapons, nerve agents may be used again as CWAs in a war or terrorist attack. Therefore, health professionals should be familiar with the medical aspects of the nerve agents and prepare for appropriate action as required.

The nerve agents are OP compounds, similar to OP pesticides, but are more toxic than the pesticides. Applying first aid kits, for example, MARK1 is important to reduce toxicity. However, atropine and oximes are the well-known antidotes for the treatment of OP nerve agents. There are several adjuvant and additional therapies including magnesium sulfate, sodium bicarbonate, gacyclidine, benactyzine, tezampanel, hemoperfusion, and bioscavengers that have recently been used for OP nerve agents and pesticide poisoning with promising effects.

The exact date of the first sulfur mustard synthesis is uncertain [1]. There are several reports on the formation of a chemical compound formed by the reaction of sulfur dichloride and ethylene in the early nineteenth century by the Belgian-French chemist César-Mansuète Despretz [2–5]. However, it is unclear whether Despretz realized the irritating or toxic properties of his newly discovered product [2]. The German chemist Albert Niemann reported in 1860 during experiments with ethylene and sulfur dichloride the formation of an oily liquid, “Even traces brought into contact with the skin, while painless at first, result in a reddening of the skin after several hours, and in the following days produce blisters which fester, heal slowly and with great difficulty, and leave behind significant scarring” [2, 6, 7]. Niemann likely suffered from sulfur mustard-induced pulmonary late effects that resulted in an early death. Almost in parallel, the British chemist Frederick Guthrie reported the same reaction [8, 9]. In 1886, the German chemist Viktor Meyer established the first reliable synthesis of pure sulfur mustard based on the chlorination of thiodiglycol, produced from chloroethanol and potassium sulfide, with phosphorus trichloride [10, 11]. This process is recognized as the “Meyer method” and has to be considered an important step toward the large-scale production of sulfur mustard [12]. The Levinstein process involved the reaction of ethylene and sulfur chloride and resulted in less pure products [3, 5, 13]. These impurities are responsible for the characteristic odor (garlic-, horseradish-, mustard-like) of non-distilled sulfur mustard [3, 5, 14, 15].

The use of chemicals for warfare can be dated to World War I. At the beginning of World War I, there was a widespread belief that the conflict would be short or, at least, would last for a few months only [16]. However, as the battle turned into a trench war, combating parties progressively ran out of conventional ammunition. Thus, other means of warfare were considered. A well-developed chemical industry, especially in Germany, resulted in an unfortunate coalition of politics and science [11, 16]. From 1914 attempts were made in a number of countries to convert harmless chemical compounds into chemical

weapons [11]. Sulfur mustard found its way onto the battlefield. Fritz Haber, director of the Kaiser Wilhelm Institute for Physical Chemistry and Electrochemistry in Berlin, was the driving force for its use. Wilhelm Lommel, an employee of the Bayer company in Leverkusen and Wilhelm Steinkopf, head of the chemical weapons research unit of Haber’s institute, investigated the toxicochemical properties of sulfur mustard in 1916. They developed a method for its mass production and prepared the agent for use in the war [16, 17]. This circumstance is the reason for the acronym “S-Lost,” representing “S” for “Schwefel” (sulfur) and the initials of *L*ommel and *S*teinkopf.

On July 12, 1917, the German artillery delivered approximately 50,000 sulfur mustard containing shells near Ypres, Belgium [18]. More than 20,000 casualties resulted from this first use of sulfur mustard as a chemical warfare agent [19]. Although sulfur mustard was introduced later in the war, it became known as the “King of Battle Gases” because it eventually caused more chemical casualties than all the other agents combined, including chlorine, phosgene, and cyanogen [19]. In summary, the use of chemical weapons such as chlorine, phosgene, and mustard gas had resulted in more than 1.3 million casualties and approximately 90,000 deaths and entitled World War I as “the chemists war” [2, 5, 19].

After the initial use of sulfur mustard in World War I, further use was reported including the Rif War in Morocco (1921–1926), the Italian–Ethiopian War (1935–1936), the Japan–China War (1939–1945), and the Egypt–Yemen War (1963–1967) [4, 11]. Fortunately, chemical weapons were not deployed in World War II, although their use was almost put into practice: Germany stockpiled nerve agents and about 25,000 t of sulfur mustard, while the USA stockpiled a total of about 135,000 t of chemical agents in 1945 [20]. As the USA did not possess nerve agents at that time, thus it has to be assumed that the majority of the US stockpiles may have been alkylating agents and lung agents. Moreover, the US Liberty ship “SS John Harvey” carried approximately 100 t of sulfur mustard and was bombed by the German Air Force during the air raid on Bari,

December 2, 1943. The destruction of the John Harvey caused the release of sulfur mustard. Eight hundred men were hospitalized, of whom 617 suffered from sulfur mustard exposure [21]. In 1981, Iraq invaded Iran (Gulf War I, 1981–1988). During that conflict, Iraq repeatedly used sulfur mustard, even against civilians [1]. Probably the most severe attack took place in 1987, when the Iraqi army delivered 1 t of sulfur mustard on Sardasht, a Kurdish town in northern Iran [22]. Today, it is estimated that about 45,000 Iranians still suffer from severe long-term health effects from these attacks [4]. Now, chemical weapons are banned by the Chemical Weapons Convention (CWC) which came into force in 1997 and has been signed by 192 member states ([23, 24] accessed on 22.02.2016). One major goal of the CWC is the destruction of all existing chemical weapons under international verification by the Organisation for the Prohibition of Chemical Weapons. Although substantial progress in the destruction of old chemical munitions, including sulfur mustard stockpiles, has occurred, there is strong evidence that terrorist groups used sulfur

mustard against Kurdish Peshmerga forces in Iraq [25]. Whether sulfur mustard was acquired from old ammunition or has been synthesized de novo is a matter of debate. However, the chemical synthesis of sulfur mustard can be achieved by simple means. Moreover, accidental exposures during the destruction and neutralization of sulfur mustard have been reported [26].

Relevant Chemistry

Sulfur Mustard

Sulfur mustard (bis(2-chloroethyl)sulfide, CAS Number 505-60-2) – also referred to as Yperit(e) with regard to its first use on the battlefield near Ypres, “Senfgas” which is the German translation of mustard gas, “yellow cross” as German sulfur mustard shells were marked with a yellow cross, H and HS (“Hun Stuff”) or HD (“Hun Stuff distilled which is also the official NATO code”) – is an oily liquid at room temperature (Table 1) [3, 27,

Table 1 Important physicochemical properties of sulfur mustard [3–5, 14, 15, 21, 27–29]

Chemical name	bis(2-chloroethyl)sulfide
Common names	Sulfur mustard
	Mustard gas
	Yperit(e)
	Senfgas
	H, HS, HD
CAS Number	505-60-2
Chemical formula	$C_4H_8Cl_2S$
Chemical structure	
Molecular weight	159.08 g/mol
Density	Solid 1.34 mg/cm ³
	Liquid 1.27 mg/cm ³
Appearance at 20 °C	Oily liquid
	Colorless to pale yellow to dark brown
Melting point	13–14.5 °C
Boiling point	217.5 °C
Solubility	Poor in water (920 mg/L at 22 °C)
	Good in organic solvents (e.g., alcohol, ether)
	Soluble in fat
Vapor pressure	0.08 mmHg at 22 °C
	0.11 mmHg at 25 °C
	0.23 mmHg at 30 °C

28]. Thus, the term mustard “gas” is imprecise although it is commonly used in general linguistics. Pure sulfur mustard is colorless. When produced in “industrial” large scale and allotted to chemical warfare, the agent is pale yellow to black brown [14, 28, 29]. Weapons-grade sulfur mustard may contain stabilizers, starting materials, or by-products formed during manufacturing and products formed from slow reactions during storage [28]. These impurities are responsible for the characteristic odor (garlic-, horseradish-, mustard-like) and color (Fig. 1) [3, 5, 14, 15]. The vapor pressure of sulfur mustard is moderate (0.11 mm Hg at 25 °C), but is high enough for it to be in air in the immediate vicinity of liquid droplets [28, 29]. At 25 °C, sulfur mustard deposited on surface soil will evaporate within 30–50 h [28]. Weather conditions (i.e., temperature and wind) will greatly affect the persistence of sulfur mustard on soil. Warm temperatures and stronger winds decrease the persistence of sulfur mustard [28]. In winter, sulfur mustard can still be detected after as long as 2 weeks [28]. Sufficient levels of chlorine in the water (e.g., salt water) will inhibit sulfur mustard hydrolysis. Moreover, stable sulfonium polymers may be formed at the outer surface of a sulfur mustard droplet in salt water. These polymers are able to accumulate, thus creating a thick boundary

layer, which prevents hydrolysis of sulfur mustard within the inner part of the droplet. Thus, sulfur mustard may persist over decades.

Nitrogen Mustards

Nitrogen mustards (HN) (Table 2) are also alkylating agents similar to mustard gas. Although HN1, HN2, and HN3 were developed for use in chemical warfare, they never found their way onto the battlefield [31]. However, during their development in World War II, scientists and physicians noted their antitumor potential, especially with regard to hematologic malignancies [32, 33]. Soon, clinical trials were started and these heralded the new age of chemotherapy [34, 35]. Other nitrogen mustards including cyclophosphamide, chlorambucil, uramustine, ifosfamide, melphalan, and bendamustine were developed and are still in use for chemotherapy [36]. Some of these substances require conversion into active substances in vivo (e.g., cyclophosphamide). Exposure to nitrogen mustards may cause a comparable clinical picture compared to sulfur mustard [3].

Pathophysiology

Although medical research for many decades has proposed several hypotheses of sulfur mustard-induced pathological effects, none of these hypotheses is considered all encompassing. It is likely that the plethora of proposed mechanisms identified so far runs in parallel and results in a complex pathophysiology, which is not completely understood [37–39].

Alkylation

Alkylating properties of sulfur mustard are well established. One of the chlorine atoms can be cleaved resulting in a carbenium ion [5, 21, 37]. This highly reactive carbenium ion is capable to cause covalent modification of various biomacromolecules including RNA, DNA, and proteins, thus altering their biological function

CAS Number	555-77-1
Chemical formula	$C_6H_{12}Cl_3N$
Chemical structure	

[21, 37, 38, 40, 41]. Well documented and comprehensively analyzed are covalent alkylations of nucleic acids [3, 5, 37, 42–44].

Experiments conducted by Brookes and Lawley demonstrating covalent binding of sulfur mustard to bacterial DNA represent the pioneering work in that field [43]. Later on, it was found that the reaction of DNA and sulfur mustard in vitro led to the alkylation of guanine bases at the N7-position, resulting in the formation of N7-(2-((2-hydroxyethyl)thio)-ethyl)guanine (“N7-HETEG”) as the most abundant adduct (Fig. 2) [42]. Other adducts were found at the N3-position of adenine bases resulting in N3(2-((2-hydroxyethyl)thio)-ethyl)adenine (“N3-HETEA”) [42]. Sulfur mustard possesses two side chains which are both highly reactive. Thus, the formation of bifunctional adducts between DNA resulting in bis(2-

(guanineethyl)sulfide) (“Bis-G”) is frequently observed [42]. A less abundant but biologically highly relevant adduct is the alkylation product of guanine at the O6-residue resulting in the formation of O6-[2-[(2-hydroxyethyl)thio]ethyl]guanine (O6-HETEG). This adduct was found to account only for some 0.1% of all adducts, but apparently this lesion is lacking repair via DNA alkyltransferases and thus has to be considered mutagenic [45]. The frequency of occurrence of these sulfur mustard–DNA adducts may vary to some extent. Investigations using high-resolution mass spectrometry techniques revealed a considerably higher rate of bifunctional adducts after sulfur mustard exposure, both in vitro and in vivo [46]. N7-HETEG occurred in 64–81%, Bis-G in 18–42%, N3-HETEA in 1.3–4.6%, and O6-HETEG in 0.04–0.62% of all DNA adducts

et al. in 1979 who demonstrated that UV light-provoked DNA lesions induced the formation of poly(ADP-ribose) and facilitated DNA repair [68]. The role of poly(ADP-ribosylation) ("PARylation") in DNA repair is complex and not fully understood. In general, PARylation is a posttranslational modification mediated by poly(ADP-ribose) polymerases ("PARPs") in response to various stimuli [54]. Two members of the PARP-family (PARP-1 and PARP-2) are activated by DNA strand breaks [54]. Most probably, PARylation represents a sensor and marker of DNA lesions and inducer of DNA repair [54, 69]. Thus, PARPs might orchestrate the delicate balance between survival and death signaling [70]. The role of PARylation in sulfur mustard cell damage has been extensively investigated [54, 71–73]. PARylation is dependent on the availability of cofactors (NAD) and energy equivalents (ATP) [68]. Thus, excessive PARylation may cause severe depletion of these indispensable cofactors with the consequence of rapid, uncontrolled cell death (necrosis) (Fig. 3). Based on that fact, Berger formulated his well-known "suicide hypothesis" which correlates cell death to the depletion of cofactors (i.e., NAD) during PARylation of DNA strand breaks [68]. With regard to sulfur mustard-induced DNA lesions, Papirmeister and colleagues postulated the occurrence of DNA strand breaks as repair intermediates triggering PARP-1 activation and subsequent loss of NAD and ATP, which resulted in cell death (Papirmeister theory) [74]. As a corollary, PARP inhibitors were tested as potential antidotes against sulfur mustard toxicity. Although PARP inhibitors were able to maintain NAD levels in sulfur mustard-exposed cell, the overall cell survival was not improved, but a shift from necrosis to apoptosis was evident [61, 75–77].

Apoptosis and Necrosis

Cell death is a key event after sulfur mustard injury. Both apoptosis and necrosis can be observed [37, 61, 62, 71, 78, 79]. At high-dose exposures, sulfur mustard predominantly provokes cell death through necrosis caused by

Fig. 3 Role of PARP during sulfur mustard-induced cytotoxicity ([37] modified). Sulfur mustard-induced DNA lesions are recognized by PARP. DNA repair or controlled cell death mechanisms are initiated when there is limited DNA damage. Excessive DNA damage results in cofactor depletion and necrosis

PARP activation and cofactor depletion. Even though recent findings also describe necrosis as an orchestrated process [80], it has to be considered as a "worst case" scenario which is barely controllable. In contrast, apoptosis is a highly controlled and regulated mode of cell death. The apoptotic machinery is driven by the activation of proteases known as caspases (cysteine-dependent, aspartate specific proteases) [81, 82]. In short, the activation of effector caspase-3, caspase-6, or caspase-7 results in cleavage of a plethora of cellular proteins. The breakdown products are embedded into membrane-surrounded apoptotic bodies, which are released into the extracellular space. These remnants are cleared by efferocytosis. In contrast to necrosis, there is no significant contact of cytoplasmic content with the environment thus preventing an inflammatory response frequently observed during necrosis. There are numerous studies demonstrating

apoptosis after sulfur exposure both in vitro [83–85] and in vivo [86, 87].

Death receptor-mediated apoptosis (also called “extrinsic apoptosis”) is initiated by binding of specific ligands (e.g., Fas ligand) to their designated receptors (e.g., Fas receptor) initiating apoptosis. This process has also been demonstrated for sulfur mustard [88–90]. Both Fas ligand and receptor were upregulated in sulfur mustard-exposed human keratinocytes, and keratinocytes lacking the Fas-associated death domain were less sensitive than wild-type cells [88]. In vivo findings underline the relevance of Fas-mediated apoptosis in sulfur mustard pathophysiology because an increase of Fas ligand was detected in the bronchoalveolar lavage fluid of sulfur mustard-exposed rats [90].

In contrast to extrinsic, death receptor-mediated apoptosis, intracellular events may also initiate apoptosis (so-called intrinsic apoptosis). Proteins of the Bcl-2 family, which regulate the mitochondrial outer membrane permeabilization (MOMP) and the release of proapoptotic mitochondrial proteins (e.g., apoptosis-inducing factor) into the cytosol can trigger apoptosis and finally lead to activation of effector caspase-3. [91] Sulfur mustard impacts the Bcl-2 family of proteins and MOMP [92].

Inflammation

A common characteristic of sulfur mustard injury is inflammation. In vitro and in vivo studies document an increase of pro-inflammatory cytokines after sulfur mustard exposure [83, 93–100]. IL1(α/β), IL6, IL8, and TNF α are key players in the pro-inflammatory response and are released shortly after sulfur mustard exposure [37, 101–103]. The number of inflammatory leukocytes (e.g., neutrophils, macrophages) increased in mouse skin after exposure to nitrogen mustard, underlining the relevance of the in vitro findings [104].

NF- κ B and mitogen-activated protein kinase pathways have been reported to be substantially involved in the regulation of pro-inflammatory gene expression after sulfur mustard injury [105, 106]. Remarkably, Nf κ B pathways were found upregulated in sulfur mustard-exposed patients [107]. Moreover, sulfur mustard increased the

expression of other pro-inflammatory proteins, e.g., cyclooxygenase (COX)-2, inducible nitric oxide synthase, or myeloperoxidase [98, 108].

Reactive Oxygen and Nitrogen Species

Superoxide ($O_2^{\bullet -}$) and hydroxyl radicals (OH^{\bullet}) represent the two major oxygen-derived radicals (reactive oxygen species (ROS)). Radical nitrogen species (RNS) contain the nitric oxide radical (NO^{\bullet}). In a biological context, both ROS and RNS are formed in normal metabolism and have important roles in cell signaling and homeostasis [109, 110]. Reactive oxygen species and RNS are generated by tightly regulated enzymes, such as NO synthase (NOS) and NAD(P)H oxidase isoforms, respectively. Depending on the micro-environment, nitric oxide (NO) can be converted to various other RNS such as nitrosonium cation (NO^+), nitroxyl anion (NO^-), or peroxynitrite ($ONOO^-$), which represents the reaction product of $O_2^{\bullet -}$ and NO^{\bullet} [110]. Thus, levels of ROS and RNS will influence each other. Moreover, catalytic or stoichiometric scavengers like GSH may intercept ROS and/or RNS and thus attenuate ROS- or RNS-induced cell damage. Reactive oxygen species and RNS have been proposed as key mediators of sulfur mustard-induced cytotoxicity [108, 111–113]. Indeed, glutathione (GSH) depletion due to sulfur mustard exposure was demonstrated both in vitro and in vivo [114, 115]. First direct evidence that radicals are involved in sulfur mustard toxicity was provided by electron paramagnetic resonance spectroscopy showing that free radical and lipid peroxidation occurred in vivo after pulmonary exposure to sulfur mustard vapors [116]. In addition, sulfur mustard-induced formation of carbon-based radicals with subsequent formation of superoxide, peroxy, and hydroxyl radicals has been shown [117]. Further, superoxide radicals derived from catalytic uncoupled endothelial NO synthase have been implicated in contributing to sulfur mustard cytotoxicity [108]. Moreover, the conjugation of GSH with sulfur mustard has been demonstrated [118, 119] and may be conducive to enhanced ROS levels.

To make matters worse, sulfur mustard decreases antioxidant enzyme activities of superoxide dismutase (SOD), catalase (CAT), and glutathione peroxidase in vivo [120], thereby aggravating ROS-induced cell damage. There are numerous reports that demonstrate the involvement of NO/NOSs in sulfur mustard toxicity [121–124]. Recent work has demonstrated mitochondrial dysfunction and mitochondrial-derived ROS as an important event in sulfur mustard pathophysiology [125–128].

Toxicokinetics

Sulfur mustard can enter the body through different routes. Absorption of the agent after skin contact and vapor absorption through the respiratory system are the two major routes of uptake [4, 40, 129]. Uptake of sulfur mustard through the gastrointestinal system or eye contact is theoretically feasible, but of minor relevance with regard to toxicokinetics. Nevertheless, local health effects would be severe [40].

Skin Absorption

The penetration rate of liquid sulfur mustard was determined ex vivo with 71–294 $\mu\text{g}/\text{cm}^2/\text{h}$ using a Franz-type glass diffusion cell [130]. Absorption through human skin was estimated with 60–240 $\mu\text{g}/\text{cm}^2/\text{h}$ [130]. There are some relevant parameters like skin thickness, hair density, and moistness that may have an impact on the absorption rate. Early reports have postulated that under nonocclusive conditions, about 80% of topically applied sulfur mustard will evaporate and only 20% will be absorbed [131]. From this fraction, 10–20% is likely to react with biomacromolecules and 80–90% reach the blood circulation [130, 131]. A depot of sulfur mustard within the lipid-rich stratum corneum is likely to exist [131]. After a 12 min application of ^{14}C -labeled sulfur mustard vapors, 90% of total radioactivity was located in the exposure skin area [132]. Occlusion of the skin after contact to sulfur mustard may result in a dramatic increase (up to 100-fold) of absorption [133].

Respiratory Absorption

The absorption of sulfur mustard through the respiratory system is a highly relevant route of entry when the agent is used in armed conflicts or in terrorist attacks. Sulfur mustard is readily absorbed in the upper respiratory tract [4, 40]. However, some studies postulate that sulfur mustard does transit the distal upper airways to promote lower airway injury [134]. Toxic lung injury of the lower airway system with alveolar epithelial injury and detachment of cells from basement membranes following exposure to mustards is frequently observed [135]. In vivo experiments in rats revealed that after a 10 min exposure toward 250 mg/m^3 ^{14}C sulfur mustard vapor, a total of 18.1 μg sulfur mustard was absorbed [132].

Distribution

In deceased victims it was found that highly lipophilic sulfur mustard accumulates in fatty tissues (Table 3) [136, 137]. The distribution of sulfur mustard can be described by using a two-compartment model with an initial α -halftime of 5.56 min and a terminal β -halftime of 3.59 h with a steady-state distribution volume of 74.4 l/kg [138].

Biotransformation

Sulfur mustard is rapidly hydrolyzed in physiological environment, resulting in the major biotransformation product thiodiglycol (TDG) [40, 139]. Thiodiglycol may further be oxidized to TDG sulfoxide which is then conjugated to glutathione forming 1,1'-sulfonylbis[2-S-(*N*-acetylcysteinyl)ethane]. Following the β -lyase pathway, the 1,1-sulfonylbis[2-(methylsulfinyl)ethane] (SBMSE) and 1-methylsulfinyl-2-[2-(methylthio)ethylsulfonyl] (MSMTESE) ethane can be formed [40]. In addition, sulfur mustard is able to react with free cysteines of various proteins [40]. Sulfur mustard adducts have been identified especially in albumin and hemoglobin [55, 140, 141] but also in other proteins e.g., cytokeratins or actin [48].

Table 3 Sulfur mustard tissue concentration in a deceased victim [136]

Tissue/Organ	Concentration (mg/kg)
Fat	15.1
Skin, including subcutaneous fat tissue	11.8
Brain	10.7
Skin	8.4
Kidney	5.6
Liver	2.4
Muscle	3.9
Cerebrospinal fluid	1.9
Spleen	1.5
Blood	1.1
Lung	0.8
Urine	Not detected
Blister fluid	Not detected

Elimination

Sulfur mustard metabolites are eliminated mainly through the renal route [132, 138, 142–144]. Eighty percent of radioactivity from ^{14}C -labeled sulfur mustard was found in urine, whereas only 3% were excreted with feces [138]. It is important to realize that distinct background levels of TDG and TDG sulfoxide can be found in the urine of healthy, unexposed persons, whereas the β -lyase pathway products were exclusively found in the urine of exposed individuals. The total clearance of sulfur mustard was calculated at 21 l/kg/h [138].

Clinical Presentation

Sulfur mustard is classified as a vesicant or blister agent. However, the agent can affect other organs or tissues. Skin, respiratory tract, eyes, and internal organs (bone marrow) are all targets of sulfur mustard toxicity. A malicious characteristic of sulfur mustard injury is the fact that contact with the agent does not immediately cause any clinical symptoms [1, 12, 20, 26]. Depending on exposure dosage and time, the onset of clinical symptoms may occur within

a few hours to up to 24 h [1, 12]. The maximum intensity of symptoms can be reached after days [12]. Sulfur mustard can cause acute, chronic, and delayed health effects.

Acute Health Effects

Skin

Sulfur mustard penetrates rapidly through normal clothing and predominantly affects moist and thin skin areas, e.g., the genital or axillae region [4, 26]. Physical stress with increased blood circulation and sweating as well as local mechanical shear stress (e.g., from a backpack) may enhance sulfur mustard-induced skin effects. The onset of cutaneous symptoms depends on the concentration of sulfur mustard vapor and exposure time (concentration * time). At higher doses symptoms occur within a few hours [4, 12, 26]. For dermal exposures, sulfur mustard vapor concentrations between 100–300 $\text{mg} \cdot \text{min} / \text{m}^3$ and liquid amounts between 10–20 $\mu\text{g} / \text{cm}^2$ have been postulated as threshold doses [12]. Beyond these concentrations, clinical symptoms will start with itching and erythema some 4–8 h after exposure (Fig. 4, Table 4). At higher doses (vapor, 1000–2000 $\text{mg} \cdot \text{min} / \text{m}^3$; liquid, 40–100 $\mu\text{g} / \text{cm}^2$), blister formation starts with the formation of small vesicles which may flow together to form large bullae [12]. Typical sulfur mustard-induced blisters are thin walled and filled with a yellowish liquid, which do not contain any agent [12]. Sulfur mustard targets rapidly proliferating keratinocytes of the basal layer in the first line. Blister formation occurs between the epidermis and dermis [145, 146]. The Nikolsky signs – which are associated with toxic epidermal necrolysis – are positive [12]. Sulfur mustard-induced blisters disrupt if they are large enough and may proceed to deep ulcerations, which are associated with wound-healing disorders [147–149]. Inflammation of affected skin areas is frequently observed [4, 12, 20, 145]. Moreover, hyperpigmentation that can last for years is also common [4, 26].

Fig. 4 Clinical presentation of an accidental sulfur mustard exposure on day 7 after exposure. Three exposure sites (thorax, middle abdomen, lower abdomen) are distinguishable. A distinct erythema and deep ulcerations at all sites are evident [150]

Table 4 Acute dermal symptoms after sulfur mustard exposure ([12] modified)

Severity	Clinical presentation

Severe	Rapid development of erythema and blisters
	Ulceration of dermal structures

Lungs

The respiratory tract is more sensitive to sulfur mustard than the skin. Sulfur mustard vapor concentrations in the range of 12–70 mg*min/m³ are able to induce clinical symptoms within a few hours [147]. The onset of symptoms correlates inversely with the dose of sulfur mustard. Acute human lung exposures to sulfur mustard can be lethal in a short period (the mortality of sulfur

mustard is stated with 2–3% [5] and is mainly attributed to acute lung injury [151]). On the other hand, exposure may also lead to chronic devastating airway or pulmonary disorders [152]. Effects of sulfur mustard on the respiratory tract from the nasal mucosa to the terminal bronchioles are dose dependent [4]. After a symptom-free period irritation of nasal mucosa, hoarseness, sneezing, and coughing are the first clinical signs of respiratory tract damage (Table 5) [12, 153]. Moderate exposure results in lacrimation, rhinorrhea, loss of smell and taste, and discharge of mucus from nose and throat [4, 12, 151]. Although sulfur mustard predominantly affects the upper respiratory tract, with increasing dose, the terminal airways may also be affected causing severe cough, dyspnea, and hemorrhage into the alveoli and lung edema [154]. A critical event is the detachment of pulmonary epithelium which mixes with mucus and edema fluid resulting in the formation of “pseudomembranes,” resembling those characteristic of diphtheria infection, which can slough and obstruct the airway with fatal consequences [151]. Severe forms of lower airway disease can be expressed as the acute respiratory distress syndrome (ARDS), with a high mortality rate [153]. Pulmonary inflammation usually develops within a few days after sulfur mustard exposure. In severe cases, bacterial superinfection and lung gangrene may occur [153].

Eyes

The eyes are the most sensitive organ with regard to sulfur mustard exposure. Clinical symptoms develop generally faster (i.e., within 1–2 h) compared to other effects, such as skin lesions [12]. Acute intoxication presents with conjunctivitis, blepharospasm, lacrimation, miosis, photophobia, eyelid edema, and severe eye pain (Table 6) [12, 147, 151]. Sulfur mustard vapor doses beyond 400 mg*min/m³ result in severe full-thickness corneal damage with ulcerations and occlusion of conjunctival blood vessels due to endothelial damage [12]. Corneal vascularization starts a few weeks later leading to pannus formation [12]. Iranian victims reported a burning sensation and pain in the eyes and throat shortly

	Hacking cough
	Tracheobronchitis
	Pseudomembranes
Severe	Edema in upper and lower airways
	Ulcerations

(within minutes) after an attack with the agent [12]. Severe blepharospasm may prevent lifting the eyelid which may be perceived as “blindness” [129]. However, recovery from conjunctivitis after mild ocular exposure (dose range of 12–70 mg*min/m³) can usually be observed within a few days [151]. Additional reports from Iranian casualties revealed that 75% of the patients presented severe (purulent) conjunctivitis [129]. Conjunctivitis (18%), opacity of the cornea (27%), and erosions and opacity of the cornea (50%) were the most severe eye complications, and only 36% of the patients showed a full recovery at discharge [129].

Systemic Toxicity

The effects of systemic sulfur mustard poisoning are very similar to those caused by radio- or chemotherapy. This is not surprising, as described earlier, alkylating chemotherapeutic agents which are still frequently used in clinical cancer therapy, originated from the alkylating sulfur mustard [4]. Low-dose exposure may result in headache, nausea, vomiting, and loss of appetite (Table 7). High-dose exposure may damage the gastrointestinal tract and the bone marrow more severely. After initial leukocytosis [155], a significant reduction of white blood cell count was reported in mustard gas intoxication by all routes of exposure [156]. This may result in severe immunosuppression due to the bone marrow

	Ulceration
	Perforation

suppression reported in patients exposed to high doses of sulfur mustard [4, 12, 151, 155, 156]. Hemorrhage, anemia, and other hematological complications are other bone marrow-related consequences [12]. Bone marrow and blood count examination of Iranian casualties revealed a toxic-infectious picture similar to the side effects of cytostatic treatment. Specifically, erythropoiesis was altered and showed signs of hyperplasia (78%) or dyschromia (44%). Granulopoiesis was suppressed (22%) or showed a left shift (33%). Megakaryopoiesis was increased in 22% of the investigated patients [129].

Chronic Health Effects

Skin

Chronic skin injury usually arises in veterans who developed blister formation and skin necrosis after sulfur mustard exposure [157]. Hyper- and hypopigmentation (poikiloderma) and dermal scarring are also frequently observed [4, 26]. Hyperpigmentation (20–55% incidence) seems to occur more often than hypopigmentation (5–25% incidence) [158]. Moreover, skin dryness is observed in formerly affected skin areas [12, 26, 151]. Persistent pruritus, burning sensations, and desquamation may occur [4, 12, 157]. Lesions characterized by erythema and edema only, without vesication and ulceration, usually do not result in chronic dermal effects [159]. Malformations of the vasculature in

Table 7 Acute systemic symptoms after sulfur mustard exposure ([12] modified)

Severity	Clinical presentation
Mild	Nausea and vomiting
	Loss of appetite
Severe	Immune suppression
	Leucopenia
	Diarrhea
	Cachexia

the form of cherry-like hemangiomas and telangiectasia have been observed in some patients [160]. Others may complain about paresthesias in formerly affected skin regions [160].

Lungs

Sulfur mustard-induced acute pulmonary lesions may directly progress to long-lasting chronic health effects [12, 151]. However, delayed onset of chronic lung injury can also be observed. It is assumed that up to 43% of Iranian veterans are still suffering from sulfur mustard-induced lung injury [161]. Remarkably, death that was related to a sulfur mustard exposure is believed to be caused by pulmonary lesions or pulmonary dysfunctions primarily [162]. Common clinical findings are chronic cough, dyspnea, and sputum production [163, 164]. Late pulmonary effects after sulfur mustard injury include obstructive and restrictive lung diseases that have been referred to as “Mustard Lung” [163–165]. The clinical picture of Mustard Lung resembles common signs and symptoms of chronic obstructive pulmonary disease (COPD). Sputum production, shortness of breath, and a productive cough occur in patients with Mustard Lung. Additionally, a reduced ratio between forced expiratory volume in 1 s (FEV1) and forced vital capacity (FVC) supports the diagnosis, especially in patients with previous blister formation [164]. Bronchiectasis, air trapping in expiration, and mosaic parenchymal attenuation are indicative of a diagnosis of bronchiolitis obliterans (BO) in sulfur mustard-exposed patients [166, 167]. However, the exact mechanisms leading to Mustard Lung have not been unraveled. Some distinct pathophysiological differences have been described, e.g., although inflammation is known as one of the main

pathogeneses involved in COPD, there is some debate whether inflammatory processes have significant contributions to the pathogenesis of Mustard Lung [165]. Chronic persistent bronchitis was reported in 59% of patients with a single severe sulfur mustard exposure. These individuals suffer from a severe morbidity [162, 168]. Pulmonary involvement has been considered the major determinant of long-term mortality and morbidity in sulfur mustard-affected individuals [169]. 20 years after sulfur mustard exposure, BO has been identified as the most prominent delayed respiratory effect [169, 170]. On the other hand, pulmonary fibrosis was also found in sulfur mustard-exposed Iranian soldiers [171]. Fibrotic remodeling of the lung may also result in significant scars and narrowing of the bronchial system, thus aggravating chronic lung injury.

Eyes

Ocular damage was diagnosed in 39.3% of sulfur mustard-exposed Iranian casualties, in particular after high-dose exposures [161]. In the chronic phase, the patients may complain of itching, burning sensation, photophobia, tearing, decreased vision, dry eye, red eye, ophthalmic pain, and foreign body sensation [151]. Chronic sulfur mustard-induced eye injury is known as “mustard gas keratopathy” (MGK) and is characterized by persistent epithelial lesions, corneal neovascularization, progressive corneal degeneration, chronic blepharitis, meibomian gland dysfunction, dry eye, perilimbal conjunctival ischemia, stem cell deficiency, epithelial irregularity, recurrent or persistent epithelial defects, corneal neovascularization, tortuous blood vessels, stromal scarring, and secondary degenerative changes including lipid and amyloid deposition [4, 172–174]. Remarkably, MGK can develop between 15 and 20 years after exposure [175, 176]. The pathophysiology of these changes is not clear. Limbal stem cell deficiency is proposed [172, 177].

In some cases, an ocular phenomenon known as delayed-type ulcerative keratitis, characterized by corneal thinning, corneal opacification and neovascularization, and corneal epithelial deficiency, may occur after a symptom-free period [151]. Delayed-type ulcerative keratitis may lead

to late-onset blindness and may even persist after corneal transplantation [151].

Cancer

The DNA-alkylating compound sulfur mustard is classified as a Group I carcinogen (definite human carcinogen) by the International Agency for Research on Cancer (IARC) [178]. There are numerous *in vitro* studies that have demonstrated mutagenic properties of sulfur mustard using phages, bacteria, fungi, protozoa, plants, or insects [4, 179]. *In vivo* experiments investigating carcinogenicity in rats and mice after sulfur mustard exposure through different routes (oral, skin, inhalation, subcutaneous or intramuscular administration) resulted in a significant increase of tumor incidence [4, 178–182]. Also *in vivo*, sulfur mustard induced micronuclei formation in mouse bone marrow cells [183]. In summary, it is established that sulfur mustard has mutagenic and carcinogenic potency in animals.

However, despite the IARC assessment, evidence for carcinogenicity of sulfur mustard in humans is mixed. Definitive evidence of the carcinogenic properties of sulfur mustard was provided by occupational exposures of individuals working in chemical warfare agent plants [182]. Studies revealed an increased incidence of different cancers, especially of the respiratory tract, in workers of Japanese, German, or British chemical agent factories [182, 184]. Workers responsible for the deconstruction of the “Heeresmunitionsanstalt St. Georgen” in Germany after WWII were inadequately equipped with protective measures [12]. Here, an increase of multiple skin tumors, such as basal cell carcinoma, Bowen’s disease, Bowen’s carcinoma, and spinocellular carcinoma, was detectable [12].

Experience from World War I revealed a positive association between a single-dose exposure and cancer development, however, with a low overall risk [182]. In an American 20-year follow-up study on World War I veterans, death rate by cancer was found at 2.5% in comparison to 1.9% in the control group. The risk of death from lung cancer among exposed men was estimated as 1.3, with 95% confidence limits of 0.9–1.9 when compared to unexposed controls [185].

A long-term follow-up cohort study on Iranian veterans revealed a significantly increased cancer incidence after exposure to sulfur mustard [186]. The incidence rate ratio of cancer was 1.81 (95% CI 1.27–2.56) and the hazard ratio of cancer was determined with 2.02 (95% CI 1.41–2.88) compared to the control group [186]. Despite the fact that the overall risk for cancer development was elevated, a statistically significant difference for specific types of cancer was not apparent between control and exposure group [186]. The described study exhibits some significant limitations: (i) the group of unexposed veterans was not matched for age, (ii) the unexposed population was not recruited on the basis of similar risk behaviors as the sulfur mustard exposure group, and (iii) data did not allow a correlation to the frequency of sulfur mustard exposure (“mostly acute and one-time exposures”) [186]. Thus, the overall results have to be interpreted with care and might underestimate sulfur mustard-induced carcinogenic effects. Remarkably, after chemotherapy with nitrogen mustard, an increased incidence of leukemia was reported [187]. A higher rate of chronic myeloid leukemia was also detected in Iranian mustard gas victims [188].

However, studies of cancer incidence in survivor populations with single, high-dose sulfur mustard exposure have thus far failed to demonstrate a strong correlation between exposure and disease occurrence [182, 189]. Nevertheless, there are hints that a single exposure to mustard agent may trigger cancer development [189].

Epigenetic perturbations may be involved in sulfur mustard-caused long-term health effects [190–193]. Recent *in vitro* and human data reveal that sulfur mustard causes epigenetic modifications (e.g., DNA hypermethylation) in skin samples of an accidental, single human exposure even 1 year after the event [192]. Epigenetic modification, in particular, aberrant promoter hypermethylation that is associated with inappropriate gene silencing, is linked with carcinogenesis [194–196].

In conclusion, it is well documented that sulfur mustard may cause cancer after long-term, chronic exposures. Some data allow the assumption that cancer might develop upon exposure toward a high single dose of sulfur mustard,

although the evidence is not very strong and definitive [182]. Nevertheless, epigenetic data derived from in vitro experiments and human exposure cases give reason to assume that single sulfur mustard may cause epigenetic perturbations comparable to those found in carcinogenesis.

Treatment

First, neither an antidote nor a specific therapy against sulfur mustard injury exists. Thus, wearing suitable protective equipment to avoid contact to sulfur mustard is important, whenever possible. If exposure is not preventable, early and thorough decontamination is critical. Decontamination of liquid skin exposures is the first-line treatment. Reactive Skin Decontamination Lotion (RSDL) and Fuller's earth or sodium hypochlorite are suitable substances for that purpose. However, although these substances are efficient for agent binding or hydrolysis, skin compatibility may be compromised. In particular, a decontaminant for wounds is not available. All suggested solutions affect wound healing to various degrees. Thus, for wounded, exposed individuals, the only method available is extensive showering with pure water at medium temperatures. High water temperatures should be avoided because vasodilatation with increase skin blood flow may facilitate absorption of sulfur mustard.

After decontamination, therapy generally is performed according to clinical signs and symptoms. As mentioned above, no specific treatment is available, but various promising symptomatic approaches have been described and are the subject of current research.

Sulfur Mustard Scavengers

The highly reactive sulfur mustard can covalently bind to cysteine residues within various sources resulting in stable alkylated products. Thus, after both reactive side chains have undergone alkylation reactions, sulfur mustard is no longer reactive or toxic. The well-tolerated GSH-precursor drug *N*-acetylcysteine may be used to provide cysteine

equivalents. *N*-acetylcysteine may either function directly as a sulfur mustard scavenger or indirectly by supporting production of GSH that in turn may scavenge the highly reactive agent [197–203]. Prophylactic administration may also be beneficial for scavenging sulfur mustard in the circulation, e.g., after redistribution from lipid depots. Other nucleophilic scavengers like 2,6-dithiopurines reveal promising effects in in vivo experiments [204].

N-acetylcysteine is well tolerated and is the antidote of choice in acetaminophen poisoning [205]. Although it does not have a regulatory approval with regard to sulfur mustard poisoning, the available experimental data may favor an off-label use with dosages equivalent to those used in acetaminophen poisoning [205]. Therefore, the routine use of NAC in sulfur mustard poisoning – especially with regard to high-dose exposure cases – is recommended. After intravenous administration of a loading dose (150 mg/kg) within 15 min, treatment should be continued with 50 mg/kg i.v. over 4 h, followed by oral administration of 70 mg/kg every 4 h for additional 72 h (Grade III recommendation). If oral administration is not feasible, intravenous administration is an alternative.

Anti-inflammatory Compounds

Inflammation is frequently observed in sulfur mustard injury, in particular after dermal exposure. Anti-inflammatory compounds like COX inhibitors or corticosteroids show beneficial effects both in vitro and in vivo [206–209]. With regard to COX inhibitors, indomethacin shows pronounced effectiveness in mitigating sulfur mustard-induced inflammation [206]. Some prodrugs of nonsteroidal anti-inflammatory drugs (NSAIDs) were also tested for their effectiveness in vivo. Inflammation and edema caused by the monofunctional sulfur mustard analogue CEES (2-chloroethyl ethyl sulfide) were significantly reduced after treatment with prodrugs of diclofenac, indomethacin, and naproxen; however, notably ibuprofen amplified the inflammation [210]. These findings were confirmed in other studies showing that a diclofenac prodrug reduced mouse ear edema after sulfur mustard exposure, whereas ibuprofen did not [211]. Our own results

also identified diclofenac as a potent pharmaceutical against sulfur mustard-induced inflammation, whereas ibuprofen aggravated cytotoxicity. In conclusion, comparatively little is known about the efficacy of anti-inflammatory drugs after sulfur mustard exposure in humans, despite the fact that these compounds are likely to be used whenever medical personnel will be confronted with sulfur mustard and the inevitable inflammation. Although the available experimental *in vitro* and *in vivo* data are limited, the use of COX inhibitors or NSAIDs for counteracting inflammation and edema in sulfur mustard poisoning appears reasonable. Whether diclofenac is the compound of first choice or other pharmaceuticals may be more effective needs clarification in further studies. At this stage, administration of extended-release tablets containing 75 mg twice a day for at least 1 week is recommended (Grade III recommendation). The use of a proton pump inhibitor should be considered to prevent diclofenac-induced mucosal ulcerations.

The use of corticosteroids in sulfur mustard poisoning is discussed controversially. In general, positive effects with regard to inflammation and edema have been described [207, 212]. However, corticosteroids may have negative impacts on wound healing and thus should be considered with caution in cases of severe sulfur mustard-induced ulcerations. The topical use in mild affected areas, limited to erythema without blister formation, is reasonable [213] (Grade III recommendation).

With regard to pulmonary sulfur mustard lesions, inhalation of glucocorticoids is often performed [214]. However, the overall benefit is debatable. There is general agreement that long-term oral administration of corticosteroids should be omitted [214].

At present, a reliable recommendation for the use of corticosteroids in acute sulfur mustard poisoning is difficult. Results obtained from different animal models implicate that postexposure treatment with corticosteroids in combination with NSAIDs results in significant protective effects *in vivo* [207, 209, 215]. The treatment, however, did not completely prevent the ensuing cytotoxic processes in the epithelial layer [207].

In conclusion, the use of corticosteroids in sulfur mustard-induced acute lung injury demonstrates beneficial effects with regard to lung edema and

inflammation in animal *in vivo* experiments [212, 216]. In addition, protective effects with regard to long-term immune activation and lung fibrosis through the early inhibition of pro-inflammatory mediators are seen in animal experiments [212]. However, whether corticosteroids may have comparable effects in humans with regard to acute sulfur mustard-induced toxic lung injury has not been investigated. Based on the current knowledge, inhalative application of corticosteroids after pulmonary sulfur mustard exposure is recommended (Grade III recommendation). Intravenous or oral administration is not method of choice.

Analgesia and Pruritus Therapy

Sulfur mustard-exposed patients usually complain about itching sensations shortly after exposure. The pathophysiology of pruritus in sulfur mustard poisoning is complex and still needs to be determined. Inflammation accompanied with the release of histamine and other cytokines is a well-established trigger. Indeed, H1-receptor antagonists demonstrate some relief with regard to itching and burning sensations after sulfur mustard exposure. Some studies show the activation of membrane-bound cation channels (i.e., transient receptor potential cation channel A1, TRPA1) [217]. TRP-channel activation is thought to be involved in the mediation of histamine-independent pruritus. Profound analgesia using COX inhibitors (see earlier discussion of anti-inflammatory compounds) is recommended as these will also counteract sulfur mustard-induced inflammation (Grade III recommendation). In some cases, more potent analgesics (e.g., metamizole, opioids) may be necessary and should be applied (Grade III recommendation).

Surgical Management of Sulfur Mustard-Induced Skin Ulcerations

In general, sulfur mustard-induced skin lesions should be handled according to treatment protocols of skin burns. Surgical intervention is usually not necessary for mild cases manifested by erythema

only. We recommend that in an aseptic environment (e.g., hospital), blister roofs be removed in order to evaluate the underlying wound to be aware of evolving infections that would be an indication for antibiotics. In the case of non-aseptic environments, blister roofs should be left intact to avoid infections. Deep ulcerations frequently exhibit delayed wound healing, often requiring surgical interventions. As laser ablation of sulfur mustard-induced skin wounds has resulted in a faster wound closure compared to non-treated ulcerations in *in vivo* animal experiments, such a strategy might be an alternative (Grade III evidence) [218–220]. In conclusion, in the case of sulfur mustard-induced nonhealing skin defects, a plastic-surgical intervention should be considered. In any case, dressings should be daily changed and wound healing should be carefully examined. We also recommend skin care with moisturizing lotions several times a day during wound healing. This may be necessary for several weeks.

Management of Sulfur Mustard-Induced Eye Affections

Patients with ocular symptoms after sulfur mustard exposure have to be treated immediately. Contact lenses have to be removed and eyes must be extensively rinsed with water or saline solutions. Corrosive decontamination solutions such as bleach must not be applied. In mild cases without keratopathy, the application of soothing eye drops is sufficient (Grade III evidence). Vaseline dressings may prevent adherence of the lids. Mydriatics should be applied to prevent synechiae (adherence of the iris to the cornea or the lens) (Grade III evidence). An ophthalmologist should be consulted.

Management of Sulfur Mustard-Induced Lung Toxicity

Toxic lung injury is a common phenomenon after sulfur mustard inhalation for which there is no specific therapy. These effects may be aggravated by bacterial infections. Life-threatening laryngeal edema and bronchospasm can occur. These require the use of bronchodilators [3]. Pseudomembrane

formation in the upper and lower airways that may block the lumen is a major problem in severe cases. Here, bronchoscopy and extensive lavage should be performed to remove the debris. Close pulmonary function monitoring is indicated. In the case of ARDS, standard therapy including positive end-expiratory pressure ventilation may be necessary (see ► [Chap. 16, “Treatment of Acute Respiratory Distress Syndrome in the Poisoned Patient”](#)).

Follow-Up Care

Sulfur mustard is responsible for a plethora of chronic health disorders including those of the respiratory system, skin, and eyes and development of cancer. Thus, patients should be monitored frequently at specialized hospital centers. A weekly follow-up for the first 4 weeks, followed by a monthly frequency for the next 6 months, and then a half-year interval for the next 2 years is recommended [26]. Thereafter, the follow-up interval should then be set individually in agreement with the patient.

Detection of Sulfur Mustard Exposure in Biological Samples

In principle, there are three strategies for the verification of sulfur mustard exposure: (i) detection of intact sulfur mustard, (ii) detection of sulfur mustard biotransformation products, or (iii) detection of sulfur mustard adducts with biomacromolecules. Procedures that meet litigable and forensic requirements demand highly specialized laboratories with regard to the analytical methods. Reliable in-field detection systems do not exist for that purpose. However, there are some indicative methods and test systems that allow a presumptive rapid in-field detection of sulfur mustard [38, 221, 222].

Detection of Intact Sulfur Mustard

The detection of intact sulfur mustard in biological matrices (i.e., urine, blood, or plasma) is challenging because of the quick hydrolysis of sulfur

mustard in aqueous environments. Therefore, sampling after a potential exposure should be conducted as soon as possible. Sodium chloride should be added to the sample to prevent the remaining sulfur mustard from further hydrolysis [40, 223]. Samples should be frozen at -20°C or below. Gas chromatography–mass spectrometry (GC-MS) methods for the detection of sulfur mustard in biological samples (i.e., urine) are available [139]. Two-dimensional electrospray ionization–mass spectrometry in single ion monitoring mode allows a reliable detection of 10 pg/mL blood or 10 pg/g tissue [224]. Liquid chromatography–mass spectrometry (LC-MS)-based methods were successfully applied to detect intact sulfur mustard in blood [225]. In general, reports on the successful analysis of non-hydrolyzed sulfur mustard in biological samples are rare, which is most probably due to the limited stability of the highly reactive agent in biological matrices. Thus, techniques addressing sulfur mustard biotransformation products, which exhibit stability for up to 1 week, have been predominantly used [57].

Detection of Sulfur Mustard Biotransformation Products

Sulfur mustard biotransformation products are eliminated via renal filtration. Thus, their detection in urine can easily be achieved [57]. The main hydrolysis product of sulfur mustard is thiodiglycol (TDG). TDG is a highly polar compound which requires derivatization into more suitable compounds before GC-MS analysis [223]. Total TDG can be determined by acidic or enzymatic hydrolysis from glucuronidated TDG. Moreover, TDG bound to proteins can be measured after release by alkaline hydrolysis [226, 227]. Oxidation of the sulfur containing biotransformation intermediates to sulfoxide or sulfone is frequently observed [228]. Thiodiglycol sulfoxide (TDGO) is best analyzed after reduction to TDG using GC-MS techniques. However, TDG can be occasionally detected at low levels in unexposed humans [229]. Therefore, the determination of TDG only is inappropriate for verification purposes. Metabolic biotransformation through β -lyase

leads to the formation of specific β -lyase biotransformation products (1-methylsulfinyl-2-[2-(methylthio)ethylsulfonyl]ethane (MSMTESE, 1,1'-sulfonylbis [2-(methylsulfinyl) ethane] (SBMSE, 1,1'-sulfonylbis[2-(methylthio) ethane] (SBMTE) and 1,1'-sulfonylbis[2-(ethylthio)ethane] (SBETE)) that are considered as unequivocal biomarkers proving sulfur mustard exposure [223, 230]. Again, GC-MS-based techniques are available to detect these β -lyase products [231, 232]. Due to the extended stability of the β -lyase products, a positive detection may be possible within 2 weeks after exposure [233]. A successful analysis of β -lyase products of sulfur mustard-exposed individuals using either GC- or LC-MS/MS-based methods in diverse biological samples (urine, blood, and blister fluid) was reported [57, 142]. Recently, the simultaneous detection of seven sulfur mustard biomarkers (bis- β -chloroethyl sulfoxide (SMO), TDG, TDGO, 1,1'-sulfonylbis-[2-S-(*N*-acetylcysteinyl)ethane (SBSNAE), SBMSE, SBMTE, and MSMTESE) in rat plasma using UPLC-MS/MS was described [234].

Detection of Sulfur Mustard Adducts with Biomacromolecules

Sulfur mustard can bond covalently to biomacromolecules like proteins and DNA [235]. Several methods for detection of sulfur mustard adducts with cysteine, valine, histidine, and aspartate/glutamic acid residues have been reported and successfully applied to verify human exposures [26, 40, 49, 228, 236]. The detection of the sulfur mustard adducts at the only accessible cysteine residue in human albumin requires enzymatic digestion of the protein, e.g., by pronase. The resulting alkylated tripeptide (Cys-Pro-Phe) has been used for detection by LC-MS/MS methods [236, 237]. However, recent reports revealed that albumin cleavage by the current available pronase result predominantly in the formation of a dipeptide (Cys-Pro) instead of the expected tripeptide [41]. Therefore, a new LC-ESI MS/MS method was established for the simultaneous detection of di-, tri-, and also tetra-peptide [41]. Sulfur mustard-induced covalent albumin modifications

Fig. 5 “Sulfur Mustard Detector” for the on-site detection of reactive sulfur mustard. (a) Negative test for sulfur mustard. (b) Positive test after sampling of sulfur mustard after application of 5 μ l with 1 mmol/L. Both tests were run accurately as indicated by the control lines

were successfully monitored in four individuals after an accidental exposure up to 90 days after the event [57]. Sensitive GC-MS/MS methods are also available to detect sulfur mustard adducts with hemoglobin after applying a modified Edman degradation releasing the alkylated N-terminal valine [56]. Additional adducts of sulfur mustard with other proteins including keratins and actin have been found by matrix-assisted laser desorption ionization coupled to time-of-flight (MALDI-TOF) techniques [48, 238]. However, analysis of these parameters for routine verification purposes is not yet established.

As described above, sulfur mustard reacts with DNA bases resulting in the formation of

four sulfur mustard–DNA adducts. The most abundant adduct, N7-(2-hydroxy-ethylthioethyl) guanine (N7-HETEG), can be detected and quantified using LC-MS techniques [42]. Comprehensive LC-MS-based methods that allow a simultaneous quantification of all DNA adducts in urine or blood have been reported [46, 57, 239]. Alkylated bases were detected from day 3 to month 1 after sulfur mustard exposure, with a maximum peak within the first week [57]. In addition to analytical techniques allowing a litigable verification of sulfur mustard exposure, methods based on antibody detection of sulfur mustard–DNA adducts have been developed (Fig. 5) [38, 222, 240–242]. A

handheld device ("Sulfur Mustard Detector," Securetec Detektions-Systeme AG, Neubiberg, Germany) for the identification of intact sulfur mustard based on an immunohistochemical method was also developed and is now commercially available [221]. Such test strip systems have several advantages, most notably the easy on-site use, the small size of the detector, and the rapid test results [221]. The developed test strip integrates into a plastic cassette containing different membranes. All materials are in capillary contact in order to allow chromatographic flow from one to the other end (lateral flow technique) [38, 221, 222]. The sampling pad contains guanine-rich oligonucleotides that are able to react with sulfur mustard resulting in the formation of N7-HETEG. After moistening of the sample pad and sampling any liquid or vapor for 30 s, the upper and lower parts of the device are reassembled. The test is started by crushing the ampule containing the assay buffer. In the presence of sulfur mustard, N7-HETEG is recognized by a gold-conjugated specific antibody. The resulting positive test line can be recognized with the naked eye. An additional control line indicates an accurate test run. This test system is able to detect sulfur mustard vapor released from a 20 $\mu\text{mol/L}$ solution and from pig skin exposed to 2 $\mu\text{mol/L}$ sulfur mustard diluted in phosphate-buffered saline. Thus, the concentrations detected were one to two orders of magnitude below vesicating concentrations. The sulfur mustard detector can provide an early warning, prompting countermeasures such as the use of protective equipment or decontamination, significantly reducing exposure, and preserving health and operational capability [222].

Digitalis poisoning is rare but may be responsible for life-threatening complications [1–3]. Intoxication may result from suicidal or unintentional ingestion of a single large dose (acute poisoning) or from accumulation during long-term dosing (chronic poisoning). Anti-digoxin-specific Fab fragments are now considered as the first-line treatment of digitalis poisoning [4–6]. However, several concerns remain including the indications, the minimal efficient dose, and the optimal mode of administration. Despite being an expensive therapy, anti-digoxin Fab fragments were considered beneficial in a cost-effectiveness analysis [7]. This antidote was shown useful not only in digoxin poisoning but also in poisonings with digitoxin, lanatoside C, and various cardiac glycosides contained in plants such as oleander, foxglove, and lily of the valley or venoms from toads and coconut crabs (*Birgus latro* L.) [8–12]. To date, different marketed safe and effective digitalis antitoxins are available including DigiFab (40 mg).

History

Assessment of anti-digoxin Fab fragments for the treatment of cardiac glycoside toxicity began with the development of specific antibodies for immunoassay. Subsequent investigations allowed determination of the fundamental mechanisms of

immunotoxicotherapy. Butler and Chen [13] first suggested that purified anti-digoxin antibodies with high affinity and specificity should be developed to treat human digoxin poisonings. Digoxin, with a molecular weight of 781 d, was too small to be immunogenic; so it was necessary to link it to serum bovine albumin to generate antibodies in immunized sheep. Highly purified antibodies were obtained by separation techniques, and in vitro and animal studies were employed to assess their ability to bind cardiac glycosides avidly [13–18]. Intact IgG anti-digoxin antibodies reversed digoxin toxicity in dogs, but excretion of the digoxin/IgG complexes was delayed, and risks of hypersensitivity reactions or secondary digoxin release were postulated. Fab fragments of 50 kd were obtained by treating these IgG anti-digoxin antibodies with papain, yielding a safer and more effective therapy [15].

In 1976, Smith and colleagues [19] described the first clinical use of digoxin-specific Fab fragments in a human. Thereafter, clinical studies dealing with large numbers of poisoned patients allowed the assessment of their safety. Since 1976, large series of cardiac glycoside poisonings treated with anti-digoxin Fab fragments have been published, including 5004 cases by Hauptman and colleagues [20], 717 cases by Hickey and colleagues [21], 278 cases by Nordt and colleagues [22], 166 cases by Chhabra and colleagues [23], 150 cases by Antman and associates [24], 67 cases by Lapostolle and colleagues [3, 6], 36 cases by Chan and coworkers [25], 34 cases by Smolarz and coworkers [26], and 28 cases by Taboulet and coworkers [27, 28]. In the observational surveillance study of 717 cases, 50% of the poisoned patients exhibited full resolution of all symptoms of digitalis toxicity, 24% exhibited a partial response, and 12% exhibited no response [21]. Lack of response was explained by an insufficient dose of Fab fragments, the presence of a moribund state, or a diagnosis other than digitalis poisoning. None of the patients without heart disease who ingested a single overdose was a nonresponder. In this study, 54% of the 56 patients who had had a cardiac arrest survived, compared with 100% mortality before

the advent of Fab. No clear relationship was established, however, between the initial dose and the response to treatment, rendering it difficult to establish an effective dose. After this report, recrudescence toxicity (atrioventricular block, ventricular arrhythmias, or asystole) was reported, with rates varying from 2.8% in the series of 717 cases [21] to 11% in the series of 28 cases (which included many digitoxin poisonings) [27–29]. Therefore, earlier use of Fab therapy, before cardiac pacing or treatment with antiarrhythmic agents, has been advocated [3–6].

Properties

Anti-digoxin Fab fragments are derived by papain cleavage (Fig. 1) of all the heterologous IgG sheep-derived digoxin-specific antibodies, leading to the removal of the F_c fragment and a substantial reduction in the molecular weight (50 kd) and the risk of hypersensitivity. As shown by radioimmunoassay of digoxin levels, anti-digoxin Fab showed high affinity for digoxin and sufficient cross-reactivity with digitoxin to be clinically useful [8]. A 40-mg vial of digoxin Fab (DigiFab) binds 0.5 mg digoxin. Because of structural similarities among all cardiac glycosides (cardenolides), anti-digoxin Fab can neutralize lanatoside C, proscillaridin, scilliroside toxins, and other glycosides found in *Nerium oleander*, toad, and crab venoms. [9–12] However, higher doses may be needed in these other glycoside poisonings due to the lower-affinity binding of Fab to these toxins.

Fig. 1 Chemical structure of anti-digoxin-specific Fab fragment

Pharmacodynamics

Immunotoxicotherapy is a toxicokinetic treatment inducing redistribution of the cardiac glycoside to the extracellular compartment [4, 5, 30]. Affinity of digoxin for Fab ($10^9 10^{11} \text{ M}^{-1}$) is greater than its affinity for the membrane-bound Na^+, K^+ -ATPase receptors. The redistribution is so rapid and complete that symptoms usually resolve within a few minutes.

Cardiac glycosides inhibit Na^+, K^+ -ATPases located on the external membrane of myocardial cells. In patients with chronic exposures, compared with patients with acute overdoses, less digoxin is necessary for the development of symptoms. [31] Reversibility of the binding of these glycosides to this molecular target has been shown with Fab fragments. Clinical studies have shown that the onset of Fab action is rapid when the Fab fragments are infused over ~20–30 min. Reversal of the toxic effects of digitalis occurs within 30–45 min after administration [5]. Most patients who responded had clinically evident improvement by 1 h after termination of infusion and had a complete response, including the resolution of hyperkalemia, by 4 h [24]. Anti-digoxin Fab fragments also quickly improved digitalis intoxication-related gastrointestinal disturbances, including ischemic colitis [32].

Pharmacokinetics

Pharmacokinetics of Digoxin-Specific Fab Fragments

Apparent volume of distribution: ~0.4 L/kg (25–54 L)

Distribution: biphasic or triphasic

Elimination half-life: ~19–30 h in patients with normal renal function, tenfold in patients with renal failure (>100 h)

Total body clearance: 24.5 mL/min

Renal clearance: 13.6 mL/min

Anti-digoxin Fab fragments are effective in digitalis poisoning by causing (1) induction of an extracellular redistribution of the toxin, (2) its

sequestration in extracellular spaces, and (3) the renal elimination of the antibody/toxin complex [4, 5, 30, 33]. Administered intravenously, these fragments bind immediately to circulating free digitalis molecules, forming complexes unable to bind to tissue digitalis receptors. After infusion of a dose containing equimolar binding sites, total serum digitalis concentration increases 5–20 times whereas unbound serum digitalis decreases to 0 within minutes. By mass action resulting from the concentration gradient from their target tissue to the interstitial and intravascular spaces, free intracellular digitalis and receptor-bound digitalis are displaced, and reactivation of membrane ATPases ensues. Ultimately, bound toxin/Fab elimination depends on renal function [34].

Serum Fab fragment concentrations exhibit a biphasic or triphasic decline, reflecting their distribution into different compartments and their excretion and nonrenal elimination. The elimination half-life of Fab/digoxin complexes is about ~19–30 h in patients with normal renal function, compared with spontaneous half-lives of 39 h for digoxin and 160 h for digitoxin. The elimination half-life of Fab/digoxin complexes is prolonged tenfold in the case of renal failure, with no changes in the volume of distribution [34]. Schaumann and colleagues [35] calculated a volume of distribution ranging from 25.4 to 54 L for anti-digoxin Fab fragments. The total body clearance of Fab fragments was estimated at 24.5 mL/min, of which 13.6 mL/min was renal clearance.

The advantages of anti-digoxin Fab fragments compared with the whole IgG antibody are a threefold increase in volume of distribution, more rapid onset of action, smaller risk of adverse immunologic effects, and more rapid elimination [36]. More recent data, based on comparisons of the volume of distribution of immunoglobulins and Fab fragments, suggested that Fab fragments might enter cells despite their molecular weight. The apparent volume of distribution of Fab fragments is greater than the volume of extracellular water [35].

After massive ingestion, serum digoxin concentration does not correlate with the myocardial concentrations, and tissue distribution occurs with

a delay of ~4–6 h. After anti-digoxin Fab fragment administration, standard serum digoxin concentration determinations measure unbound and bound digoxin. Methods using ultrafiltration make free digoxin measurements possible. After infusion of sufficient doses of Fab fragments, the unbound digoxin concentration decreases to an undetectable level, with a reappearance 5–24 h later, depending on the dose, the infusion technique, and the patient's renal function. All studies with pharmacokinetic data showed that free digoxin concentration fell to almost zero within a few minutes following the administration of anti-digoxin Fab fragments [5]. There is no evidence of dissociation of the Fab/digoxin complex over time. The rebound in free digoxin concentrations is secondary to Fab's leaving the vascular space, digoxin's effluxing from the tissues, and possibly continued gastrointestinal absorption.

The institution of a maintenance infusion after the loading dose reduces the early reappearance of free digoxin. The loading dose immediately binds digoxin present in the vascular space and the digoxin that is redistributed rapidly to the vascular space. The maintenance dose provides enough Fab fragments to capture digoxin redistributed from the tissues into the serum. The risk of too rapid an infusion is that elimination of Fab occurs before redistribution of digoxin from its binding sites. In this case, the total amount of Fab fragments effectively bound to digoxin is less than that predicted [35].

Special Populations

Neonatal and Pediatric Patients

Pediatric patients with no underlying heart disease generally tolerate higher doses of digoxin than do adults. The administration of anti-digoxin Fab fragments is indicated in infants and young children with ingested digoxin doses of greater than or equal to 0.3 mg/kg, underlying heart disease, serum digoxin concentration greater than or equal to 6.4 nmol/L (≥ 5 ng/mL), life-threatening arrhythmia, hemodynamic instability, hyperkalemia (≥ 6 mmol/L), or

rapidly progressive toxicity [37–41]. Pediatric patients with chronic exposure may be treated successfully with small doses of Fab because of their small body burden of digoxin, whereas acute overdose requires quantities similar to those in adults.

Elderly Patients

The elderly are at relatively greater risk for severe digitalis intoxication [20, 42]. Age 55 years and older has been shown to be associated with an increase in mortality rate [31]. Anti-digoxin Fab fragments are also useful for digoxin-induced acute psychosis (digitalis delirium), characterized by severe agitation, delusional thinking, and assaultive behavior. Recent insights from a national hospital database clearly showed the necessity to improve digoxin poisoning diagnosis and management in this population [20]. Predictors of anti-digoxin Fab fragment use were emergent admission, hyperkalemia, arrhythmia associated with digoxin toxicity, acute renal failure, or suicidal intent. The majority (78%) of anti-digoxin Fab fragments were administered on days 1 and 2 of the hospitalization, while 10% of the patients received the treatment after day 7. Surprisingly, digoxin was reused after anti-digoxin Fab fragment administration in 14% of cases.

Pregnant and Breastfeeding Patients

Although digitalis passes through the placenta, few data are available on embryonic or fetal toxicity. Fab transplacental passage is poorly understood. Pregnant patients with acute digitalis overdose should be treated similarly to nonpregnant patients. In case of in utero exposure, the efficacy and safety of anti-digoxin Fab fragments for the fetus are not documented. Fetal cardiac rhythm should be monitored, and, if necessary, the fetus can be delivered and Fab administered to the neonate, as indicated by clinical signs and blood levels. Digitalis compounds are excreted in breast milk.

Renal Insufficiency Patients

Patients with renal failure on dialysis respond to Fab treatment in a manner similar to that in patients with normal renal function [24]. A theoretical possibility exists, however, that digoxin could be released with recurrence of toxicity because of decreased clearance of anti-digoxin Fab fragments. In the case of anephric patients, anti-digoxin Fab fragments are effective, although symptoms may recur 7–14 days later, indicating the need for an additional dose. Among 18 patients with a pretreatment serum creatinine of ≥ 4 mg/dL, including five patients on dialysis, recurrence of toxicity was observed only in one dialyzed patient. A multivariate analysis performed on the series of 717 cases did not show an increased risk of recrudescence toxicity in patients with renal failure [21]. The rebound in digoxin concentration is delayed in patients with renal dysfunction, presumably secondary to a prolonged distribution phase, and serum anti-digoxin Fab fragment concentrations remain detectable for 2–3 weeks, with a parallel decline in total digoxin serum concentration [34].

Recently, the international EXTRIP work group published a systematic review and recommendations on the extracorporeal treatment for digoxin poisoning [43]. Based on data from 84 patients including six fatalities, they concluded that digoxin is slightly dialyzable (level of evidence = B, using their system) and that ECTR is unlikely to improve the outcome of digoxin-toxic patients whether or not anti-digoxin Fab fragments are administered. Despite the lack of robust clinical evidence, they recommended against the use of ECTR in cases of severe digoxin poisoning when Fab fragments were available (1D) and also suggested against the use of ECTR when Fab fragments were unavailable (2D).

Contraindications

There are no known contraindications, apart from allergy to sheep immunoglobulin. No interactions with other medications have been reported.

Precautions

Considering the risk of allergy, particularly in cases of repeated administration, manufacturers recommended intracutaneous or conjunctival allergy tests before Fab fragment administration. Most toxicologists believe that the risk of sensitization to sheep Fab fragments is low and that such testing is unnecessary. After infusion, patients require close monitoring because a second dose may be necessary if toxicity recurs or fails to resolve. In non-digoxin digitalis poisoning, required doses of Fab fragments may be higher, as reported in the case of a child poisoned after ingesting yew berries, which contain taxine, a cardiac glycoside [16]. Recurrence of toxicity is infrequent, and its exact mechanism still is not understood fully. There is no evidence to support a dissociation of the Fab/digoxin complexes over extended periods [44, 45]. Recrudescence toxicity seems to be related to redistribution of free digoxin into the serum. Compatible clinical signs are not always accompanied by an increase in unbound digoxin concentrations, however.

Adverse Effects

Safety of a single low dose of anti-digoxin Fab fragments was assessed in multiple case series involving more than 7000 patients, with rare adverse effects [3, 4, 20–28]. Mild hypersensitivity reactions, including pruritic rash, facial swelling and flushing, urticaria, thrombocytopenia, shaking, and chills, rarely (~0.8%) occurred in the treated patients. Because anti-digoxin Fab fragments are obtained from bovine serum, there is a theoretical possibility of sensitization [46]. The likelihood of allergic reaction was greater in patients with allergy or asthma history [21]. Results of skin testing before Fab treatment were reported in 94 patients and were uniformly negative except for one patient who developed erythema without wheal or induration [24]. One patient received Fab three separate times over the course of 1 year as treatment for attempted suicide by digitalis ingestion, with no evidence of adverse effects [47]. No cross-

reactivity was noted with endogenous steroids that have structural similarities to digoxin.

Adverse reactions caused by rapid reversal of the effects of digitalis, such as accelerated ventricular rate in atrial fibrillation, worsened left ventricular function, or hypokalemia, were noted in 7% of 717 treated patients [21]. In a several-hour-old neonate, hypokalemia, worsening of congestive heart failure, and transient apnea were reported [24].

Administration

The efficacy of anti-digoxin Fab fragments in decreasing the mortality rate of digitalis intoxication has not been proved by randomized controlled trials. Only one randomized controlled trial was published regarding the treatment of yellow oleander poisoning, demonstrating an early improvement in cardiac rhythm and hyperkalemia from anti-digoxin Fab fragments and thus prompting its early termination [48] (Level 1 evidence). Otherwise, data on anti-digoxin Fab fragments in digitalis poisoning are limited to observational data, so the efficacy and indications for anti-digoxin Fab are uncertain [4, 11] (Grade II-2 evidence). Recent observational data supported an effect in acute digoxin poisoning, but a clinically meaningful effect in chronic digoxin poisoning was questioned [5]. The mortality rate ranged from 4.6% to 41% before availability of Fab fragments [1, 2] and remained between 6% and 29% after their availability [6, 24, 26]. These results raised questions regarding the accuracy of diagnosis, the selection of patients to treat with the antidote, and the amount and dosage regimen of Fab administration. Recently, in a case series of 147 patients in a center without access to anti-digoxin Fab fragments, of whom 70% had nausea/vomiting, 52% had ECG changes, and 43% had indications for anti-digoxin Fab, mortality was low at 1.4%, questioning the antidote usefulness, although the reported mean digoxin concentration of 4.3 ng/mL (5.5 nmol/L) in this series was much lower than expected from the reported dose [49]. Consistently, in a national hospital database including 88% >65-year-old patients admitted with digoxin overdose, there was no difference for in-hospital mortality or length

of stay among patients who received anti-digoxin Fab fragments within 2 days of admission and those who did not [20].

Fab administration initially was restricted to patients exhibiting actual or potentially life-threatening cardiac rhythm disturbances or hyperkalemia caused by digitalis intoxication when these conditions were refractory to treatment with conventional therapeutic modalities. The notion of administering conventional therapy, which resulted in delays in Fab fragment administration, was called into question [27, 28]. Delaying the administration of Fab fragments by waiting for the appearance of life-threatening symptoms may preclude their benefit. Therefore, current accepted indications of anti-digoxin administration include patients who have life-threatening tachy-/bradyarrhythmias, hyperkalemia (>6 mmol/L), or hemodynamic instability with an elevated digoxin concentration (>2 ng/mL or 2.6 nmol/L) [5]. However, the decision to administer digoxin Fab fragments should take into account their known safety versus the persistently high mortality of digitalis poisoning and possibly treat more patients at risk. Because many adult overdoses are polypharmaceutical, it is important to consider other toxicants in patients not responding to this antidote.

Dose

The lowest effective digoxin Fab dosing regimen has not been established [5]. The dose of Fab fragments is usually calculated on a molar basis to be equal to the amount of digoxin or digitoxin in the body (see table) [24]. The body burden of cardiac glycoside may be calculated using either the supposed ingested dose or the serum digitalis concentration. Experimental data showed the efficiency of Fab doses in full stoichiometric equivalence. However, the accuracy of these calculations is questionable for many reasons. The ingested dose frequently is not known with accuracy. Calculation of the number of vials from the ingested amount also may overestimate the dose of needed Fab because loss of digitalis may result from vomiting and gastrointestinal decontamination. The measured

plasma concentration of digoxin accurately reflects the body load, but only after equilibration, which requires at least 6 h after the last dose. The volume of distribution of digoxin also may be smaller in certain diseases (e.g., kidney injuries, hypothyroidism). It is unclear whether the theoretical equimolar dose is attained or exceeded. The necessity of administering an equimolar dose of Fab to obtain an initial beneficial response is not supported by the literature [2, 3, 21]. Initial response to therapy generally is favorable, with doses below the equimolar ratio, whereas the risk of recrudescence toxicity is more frequent if less than 50% of the estimated full neutralizing dose was administered. If initial administration of Fab fragments fails to reduce digitalis-induced arrhythmias, another dose should be administered.

Recently, dosing regimens based on much lower initial doses have been proposed, with 40 mg (one vial) for chronic poisoning and 80 mg (two vials) for acute poisoning, to be repeated after 60 min if inadequate response or recurrence or earlier if there is a clinical deterioration [5]. Larger initial doses, including that which will achieve full neutralization, were recommended only in peri-arrest patients. Consistently, the recent prospective observational DORA study demonstrated the effectiveness of only 1–2 vials of anti-digoxin Fab fragments to bind all free digoxin in chronic digoxin poisonings [25] (Grade II-2 evidence). However, moderate improvement in heart rate and potassium following the antidote administration was frequently observed, suggesting that bradyarrhythmia and hyperkalemia in the chronically poisoned patients could be related to other comorbidities including chronic renal failure, heart diseases, and medications like β -adrenoceptor blockers and calcium antagonists. In France, a strategy based on the early administration of a half-molar dose of digoxin Fab rather than that of the equimolar dose, usually recommended in life-threatening poisoning, was shown efficient to reduce mortality in digitalis poisoning by preventing further worsening of toxicity in patients with poor prognosis, even if they were initially not or only mildly symptomatic [6, 50]. Poor prognosis is defined by the presence of at least three of the following criteria in the absence

of any life-threatening toxicity: (1) male gender; (2) age of greater than 55 years; (3) underlying heart disease; (4) bradycardia with second- or third-degree atrioventricular block; (5) heart rate between 40 and 60/min refractory to administration of 1 mg of atropine, regardless of the conduction disturbances; and (6) hyperkalemia of greater than 4.5 mmol/L. These prognosticators, determined in the early 1980s when the ratio of acute digitoxin versus digoxin poisonings was 10/1 [51], are also currently used in chronic poisoning; however, prophylaxis is usually indicated if at least one of the final three criteria is present.

In contrast, in yellow oleander poisoning, dosing is higher because of the inability in contrast to digoxin to quantify adequately the body burden based on blood tests and perhaps lower cross-reactivity. A dose-response study recommended a dosage of 1200 mg [48]; however, subsequent data suggested that 800 mg may be effective [52, 53].

Calculation of Dosage of Fab Fragments from Body Load of Glycoside

From the ingested amount, if the amount and type of digitalis are known:

$$Q = IA \cdot A$$

Q = Body load of glycoside (mg)

IA = Ingested amount of glycoside (mg)

A = Digoxin bioavailability (0.6) or digitoxin bioavailability (1)

From the serum glycoside concentration, if the steady-state serum concentration is known:

$$Q = SGC \cdot Vd \cdot Wt \cdot 10^{-3}$$

Q = Body load of glycoside (mg)

SGC = Serum glycoside concentration (ng/mL)

Vd = Distribution volume: 5.61 L/kg (digoxin) or 0.56 L/kg (digitoxin)

Wt = Patient weight (kg)

Conversion factors:

$SGC \text{ (nmol/L)} \times 0.781 = SGC \text{ (ng/mL) for digoxin}$

$SGC \text{ (nmol/L)} \times 0.765 = SGC \text{ (ng/mL) for digitoxin}$

(continued)

Determination of the number of 40-mg vials needed*: $Q/0.5$

Empirical dosing recommendations with 40-mg vials (according to the authors):

Acute ingestion (adult): 2–4 up to 10–20 vials

Chronic ingestion (adult): 1–2 up to 3–6 vials

Note: For some authors, low dosage at least as starter should be sufficient; calculated full neutralizing doses of digoxin Fab are expensive and may not be required.

*Fab fragment dose (mg) = [molecular weight Fab (50 kd)/molecular weight digoxin (781 d)] × body load (mg). Using this calculation, 0.5 mg of digoxin is neutralized by each 40-mg vial of Fab fragments.

Route of Administration

Antidigitalis Fab fragments should be diluted in sterile isotonic saline solution and administered intravenously in a monitored setting. When reconstituted, the preparation should be used immediately or, if refrigerated, within 4 h. The dosage regimen initially proposed included the administration of the dose of Fab fragments over 15–30 min. However, increasing the duration of Fab infusion was recommended to optimize the binding of digoxin to anti-digoxin Fab fragments [35, 48]. Schaumann and colleagues [35] recommended a loading dose of four to six vials, followed by 0.5 mg/min for 8 h. The optimal dosage regimen using the minimal effective dose remains to be determined. More recently, based on pharmacokinetic modeling [5], it was suggested to administer (1), *in acute poisoning*, a small bolus of 80 mg (2 vials) digoxin Fab fragments, repeated if necessary and titrated against clinical effects and (2), *in chronic poisoning*, a small bolus of 40 mg (1 vial) digoxin Fab fragments at a time and repeated after 60 min if there is no response.

Atropine (*D,L-hyoscyamine*) is a naturally occurring racemic mixture of an alkaloid obtained from solanaceous plants, such as *Atropa belladonna* (deadly nightshade) and *Datura stramonium* (jimson weed). Pharmacologic preparations are also a racemic mixture, with the *l*-isomer possessing the characteristic antimuscarinic action. Preparations of plant extracts containing atropine have been used for centuries, both medicinally and as poisons [1]. As an antidote, atropine is the cornerstone for treating organophosphate (OP) and carbamate insecticide poisoning and OP military nerve agent poisoning. In addition, atropine is a therapeutic cycloplegic, antispasmodic, inhibitor of secretions in the respiratory and alimentary tracts, and vagolytic, leading to the use of this drug to treat symptomatic bradycardia.

Pharmacodynamics

Muscarinic acetylcholine receptors are located throughout the central nervous system (CNS), primarily in the brain, at end organs innervated by the parasympathetic division of the autonomic nervous system, and in the skin at postganglionic sympathetically innervated sweat glands. The normal, physiological endogenous agonist at all muscarinic receptors is acetylcholine. The quaternary

R.N.E. French (✉) • F.G. Walter (✉)

Arizona, Tucson, AZ, USA
e-mail: rfrench@aemrc.arizona.edu; frank@aemrc.arizona.edu

nitrogen in acetylcholine binds to the aspartate residue in all five muscarinic acetylcholine receptor (mAChR) subtypes (M_1 – M_5) to produce mAChR activation, which is described in the next paragraph. This ability to induce a change in the resting physiology of a living organism is referred to as *physiological efficacy*. The acetylcholine-binding site is a ligand-binding pocket formed by a series of seven trans-membrane helices [2]. The five mAChR subtypes (M_1 – M_5) are believed to have similar binding sites.

Upon activation by acetylcholine binding, muscarinic receptors couple to heterotrimeric guanine nucleotide-binding proteins (G proteins) to regulate second messengers and ion channel activities [3]. All known mAChRs are prototypical members of this superfamily of G protein-coupled receptors. The odd-numbered subtypes (M_1 , M_3 , and M_5) are linked primarily to G proteins of the Gq/11 class that mobilize phosphoinositides to generate inositol 1,4,5-trisphosphate and 1,2-diacylglycerol, by activating phosphoinositide-specific phospholipase C β , thereby increasing intracellular calcium. The even-numbered subtypes (M_2 and M_4) are linked primarily to G proteins of the Gi/o class that inhibit elevated adenylate cyclase activity and prolong the opening of potassium channels, nonselective cation channels, and transient receptor potential (TRP) channels [3–5]. In addition, mAChRs are capable of activating other signaling pathways depending on the cell type. M_1 , M_3 , and M_5 receptors can stimulate pathways involving phospholipase A2, phospholipase D, and tyrosine kinase, as well as calcium channels. M_2 and M_4 receptors can also use phospholipase A2 as a second messenger [6, 7].

Atropine is a competitive mAChR antagonist at all five mAChR subtypes. Because atropine is a competitive antagonist, it has no *physiological efficacy* at mAChR; however, atropine can antagonize acetylcholine binding with therapeutic, *pharmacological efficacy*. As this antagonism is competitive, it can be

overcome by larger concentrations of acetylcholine; the therapeutic implication is that atropine dosing must be titrated to the desired therapeutic effect.

In typical therapeutic doses, atropine's CNS effects are minimal; however, larger doses can cause excitation, delirium, and hallucinations. Low, subtherapeutic (<0.01 mg/kg or ≤ 0.5 mg in the average adult) doses of atropine can, paradoxically, cause decreased heart rate due to antagonism at presynaptic M1 receptors in the sinoatrial node. This inhibits negative feedback of acetylcholine, causing paradoxical release of acetylcholine that decreases heart rate [1, 8, 9]. This slowing is usually moderate, approximately four to eight beats per minute, and does not usually cause clinically significant decreases in cardiac output or blood pressure [1]. In therapeutic doses (0.5–2.0 mg in an average adult), atropine has the more expected effect of tachycardia due to blockade of the M2 receptors on the myocardial sinoatrial nodal pacemaker cells, antagonizing parasympathetic tone to the heart.

Respiratory effects of atropine include bronchodilation, drying of mucous membranes, and inhibition of secretions in the nose, mouth, pharynx, and bronchi. Other effects can include mydriasis, urinary retention, slowed GI motility, and decreased sweating [1].

Antagonism of clinically significant bronchospasm and bronchorrhea is the usual therapeutic end points to allow adequate ventilation and oxygenation of patients with severe OP or carbamate poisoning. Antagonism of OP- and carbamate-induced bronchospasm and bronchorrhea is critical because resistance to flow of a gas through a tube is proportional to $1/r^4$ and flow of a gas through a tube is proportional to r^4 , where r represents the radius. In other words, small changes in bronchiolar radius due to bronchospasm or bronchorrhea may have large effects on ventilation and oxygenation.

Pharmacokinetics

Elimination (β) $T_{1/2}$	Children < 2years	6.9 \pm 3.3 h [10, 11]

	Intraocular	8 min [15] ^e
Hepatic plasma clearance		519 \pm 147 mL/min [16]
Renal plasma clearance		656 \pm 118 mL/min [16]

^aTmax was 0.19 \pm 2.3 h, after 2 mg IM injection of atropine sulfate with AtroPen[®] auto-injector [12]. Tmax was 0.5 h after 1.67 mg IM injection of atropine free base with AtroPen[®] auto-injector; however, the first samples were collected at 0.5 h [13]

^bTmax was 41.7 \pm 19.1 min after IM injection of 0.02 mg/kg of atropine sulfate [11]. Tmax was seen 30 min after IM injection of 1 mg atropine sulfate [14]

^cTmax was 34 \pm 23 min after subcutaneous injection of 0.02 mg/kg of atropine sulfate [11]

^dTmax was 0.25 \pm 0.47 h after a 1.95 mg inhaled dose from an atropine dry powder inhaler [12]. Tmax was 0.6 \pm 0.2 h after a 5.2 mg inhaled dose of atropine sulfate suspension and 1.9 \pm 1.5 h after a 3.4 mg inhaled dose of atropine sulfate suspension [13]

^eTmax was 8 min in eight patients who received 40 μ l of 1% atropine ophthalmic solution unilaterally to the inferior sulcus of the eye; however, the first samples were collected at 8 min [15]

Intravenously administered atropine has an initial distribution or (α) $T_{1/2}$ of about one minute, after which the concentration declines rapidly within the first 8–10 min. Ten minutes after IV injection, the amount of atropine that is present in the circulation is less than 5% of the intravenously administered dose [11, 14, 17]. After IV injection, over 50% of the drug is eliminated unchanged in urine [18].

After IM injection, peak plasma concentrations are reached by approximately 30 min; absorption is faster from the deltoid muscle than from the vastus lateralis or the gluteus maximus muscles [17]. The plasma concentration one hour after IM administration is virtually equal to the plasma concentration seen with the IV route one hour after IV infusion. Approximately one third of an IM dose of atropine is eliminated unchanged in urine [18, 19].

Inhaled atropine is being developed as a systemic and pulmonary treatment for the extended recovery period after chemical weapon exposures [12]. Dry powder inhalation is a high bioavailability route for attaining rapid and consistent systemic concentrations of atropine [12]. Atropine via metered-dose inhaler was investigated in a study in which eight subjects received 1.7, 3.4, and 5.2 mg of atropine sulfate by inhalation and 1.67 mg of atropine free base (equivalent to 2 mg of atropine sulfate) by IM injection [13]. Serum atropine sulfate concentrations were measured over a 24-h period. Mean peak concentrations were 4.9, 6.1, and 7.9 ng/mL for the inhaled doses and 8.4 ng/mL for the IM dose. Typical anticholinergic effects were seen after all doses [13].

Atropine is metabolized stereoselectively, predominantly in the liver. The biologically active enantiomer (*l*) is metabolized, whereas the biologically inactive enantiomer (*d*) is excreted unchanged in urine. The four atropine metabolites that have been identified in urine are tropine, noratropine, atropine-*N*-oxide, and tropic acid [20]. Metabolism of atropine, by microsomal monooxygenases, appears to be inhibited by organophosphate insecticides; no atropine metabolites were found in the urine of eight

organophosphate-poisoned patients who received high-dose atropine [21]. Children < 2 years of age and adults \geq 65 years of age have longer elimination half-lives than older children and adults < 65 years of age [10].

Contraindications, Adverse Effects, and Precautions

There are no absolute contraindications to administering atropine for treating life-threatening, cholinergic manifestations of OP or carbamate insecticide poisoning or OP military nerve agent poisoning. However, there are relative contraindications, potential adverse effects, and precautions about which the practitioner must be vigilant. Atropine is not indicated in those who lack significant muscarinic effects after exposures. Allergic reactions to atropine eye drops and anaphylaxis to IV atropine, administered during anesthesia, have been reported [22–24].

As of December 2014, the US Food and Drug Administration (FDA) requires removal of pregnancy categories from human prescription drug product labeling. Nevertheless, some references still list atropine preparations as pregnancy class B (animal reproduction studies have failed to demonstrate a risk to the fetus and there are no adequate and well-controlled studies in pregnant women) [25, 26], whereas others list it as pregnancy class C (animal reproduction studies have shown an adverse effect on the fetus and there are no adequate and well-controlled studies in humans, but potential benefits may warrant use of the drug in pregnant women despite potential risks) [27–30]. Atropine crosses the placenta and reaches the fetal circulation; in one study, atropine concentrations in the umbilical vein were 93% of maternal values, 5 min after intravenous injection [31]. With OP or carbamate poisoning, the dose required to effectively treat the mother is probably the optimal approach since usually the best treatment for the fetus is the best treatment for the mother.

Between November 1990 and March 1991, 268 children under the age of 16 years received injections of atropine from auto-injectors that had been distributed to the Israeli population in personal aid kits. In most of these exposures, the atropine was injected accidentally, typically into a finger or hand. In some instances, the auto-injector was administered by a parent under the false assumption of nerve agent exposure. Of the 240 atropine exposures for whom data were available, 43% had dilated pupils, 39% had tachycardia, 35% had dry mucous membranes, 20% had flushed skin, 4% had hyperthermia (defined as greater than 37.8 °C), and 5% had neurological abnormalities (described variously as irritability, agitation, confusion, lethargy, or ataxia). There were no reported fatalities, seizures, or life-threatening dysrhythmias; however, 22 had tachycardia between 160 and 190 beats per minute. Five were hospitalized for observation due to tachycardia or agitation [32].

The plasma elimination half-life is prolonged in patients \geq 65 years of age [10, 11]. Delirium, urinary retention, constipation, and ileus are potential adverse effects that are potentially more troublesome in the elderly. In the setting of OP or carbamate poisoning, renal or hepatic dysfunction is not a contraindication for atropine administration, and the dose should be titrated to achieve clinical therapeutic end points.

Treatment

As an antidote, atropine is used to treat OP and carbamate insecticide poisoning and poisoning from OP military nerve agents. Atropine has also been used therapeutically as premedication to prevent oropharyngeal secretions during anesthesia, to prevent vagal mediated bradycardia in procedures such as rapid sequence intubation, as a cycloplegic for a variety of ophthalmologic conditions and for treating diarrhea, irritable bowel syndrome, myasthenia gravis, vestibular disorders, and asthma.

Administration

Atropine is available as oral, parenteral, and ophthalmic preparations, as well as in solution for use in nebulizers. As an antidote, IV and IM are the preferred routes of administration. Intraosseous (IO), subcutaneous (SC), or endotracheal administration is possible. Atropine is formulated and supplied in multiple concentrations, which increases the possibility of dosing error. The most common concentrations are 0.05 mg/mL, 0.1 mg/mL, 0.4 mg/mL, 0.4 mg/0.5 mL, and 1 mg/mL. Preservative-free formulations are preferred for dosing that requires multiple boluses or continuous IV infusions because of the theoretical concern for toxicity from accumulation of benzyl alcohol [33].

Consensus does not exist as to the appropriate dosing regimen for cholinergic poisonings. Recommendations have varied widely; 33 different regimens were identified in a 2007 review of the topic [34] (level of evidence: III). There has been a recent trend recommending the increased speed of dose escalation [35] (level of evidence: III). A titrated dosing regimen has been proposed that involves administering an initial adult loading dose of 1.8–3 mg of atropine IV. The dose is then doubled every 3–5 min with the therapeutic end point of atropinization: defined as a clear chest on auscultation, heart rate greater than 80 beats per minute, pupils no longer pinpoint, dry axillae, and systolic blood pressure greater than 80 mmHg [36, 37] (level of evidence: II-2). The presence of small pupils alone does not warrant continued administration of bolus dose atropine if the other physiologic parameters have been met. Initial atropinization, followed by an atropine infusion starting at 10–20% of the total initial bolus per hour [37], produced fewer signs of atropine toxicity, such as delirium or hallucinations, compared to ad hoc dosing [36] (level of evidence: II-2).

For IM administration, generally under field conditions rather than in an ICU setting, a combined auto-injector that contains 2.1 mg atropine plus 600 mg pralidoxime chloride is available, as

Table 1 Classification of OP or carbamate insecticide or OP nerve agent-induced signs and symptoms

are atropine-only auto-injectors in 0.25 mg, 0.5 mg, 1 mg, and 2 mg doses. The package inserts and Advanced Hazmat Life SupportTM recommends administering atropine by IM auto-injector based on the age or the size of the patient and on the presence of signs or symptoms of toxicity (Tables 1 and 2) [8, 27–29] (level of evidence: III). For adults and children who weigh ≥ 40 kg with ≥ 2 mild signs of toxicity, administer one combined auto-injector as an initial dose; for those with any severe sign or symptom, administer three combined auto-injectors as an initial dose [8, 27, 28] (level of evidence: III). Table 2 details a weight- or age-based dosing regimen for administering atropine-only auto-injectors to children [8] (level of evidence: III).

Initial doses of atropine greater than 100 mg may be needed to achieve atropinization for OP and carbamate insecticide poisonings; more than 1000 mg may be required over the first 24 h to maintain atropinization. Such quantities may

Table 2 IM administration of atropine-only auto-injectors to pediatric patients

Pediatric patient weight and age	Initial IM dose of atropine for those with two or more mild carbamate or OP-induced signs or symptoms	Initial IM dose of atropine for those with any severe carbamate or OP-induced sign or symptom
≥41 kg ≥90 lb Generally ≥ 10 years of age	2 mg	6 mg
18–41 kg 40–10 lb Generally 4–10 years of age	1 mg	3 mg
7–18 kg 15–40 lb Generally 6 months to 4 years of age	0.5 mg	1.5 mg

deplete a hospital of its supply [38]. The US Department of Health and Human Services, through state, local, and tribal governments, has prepositioned atropine auto-injectors and multidose vials for use by emergency medical services or hospital personnel for multiple casualties produced by OP or carbamate insecticide poisonings or an attack with a military nerve agent [39]. Such supplies can be accessed through the state, local, or tribal health department or the regional poison control center.

Calcium edetate (calcium disodium ethylenediaminetetraacetic acid [EDTA]) is the generic name for the chelating agent calcium disodium ethylenediaminetetraacetate. The drug also has been called *calcium disodium edathamil* and edetate calcium disodium. It is marketed in the United States under the brand name Calcium Disodium Versenate. (*Note:* Calcium edetate should not be confused with the disodium, trisodium, or tetrasodium salts of EDTA, which do not contain calcium and which may cause dangerous hypocalcemia.)

History

In 1950, EDTA (edetic acid), an industrial chemical widely employed to chelate cations in solution, was used clinically in the treatment of hypercalcemia. In 1952, investigators reported the first use of the calcium disodium salt of ethylenediaminetetraacetate (calcium edetate) in the treatment of lead intoxication in children [1] and adults [2]. The use of calcium edetate was associated with large increases in the urinary excretion of lead without the risk of hypocalcemia that had been encountered with the use of edetic acid. Within a few years, numerous accounts of the clinical utility of calcium edetate in the treatment of lead poisoning appeared in the medical literature. Its clinical use for this purpose has continued to the present.

Fig. 1 Chemical structure of calcium disodium edetate

Chemical Properties

Calcium edetate ($\text{C}_{10}\text{H}_{10}\text{CaNa}_2\text{O}_8 \cdot \chi \text{H}_2\text{O}$; molecular weight 374.27 g/mol [anhydrous]) (Fig. 1) is a white, crystalline powder that is freely soluble in water. The compound forms stable, water-soluble complexes, or chelates, with numerous cations. Because the stability constant of the lead EDTA chelate ($K_{K2} = 18.2$) greatly exceeds that of the calcium EDTA chelate ($K_{K2} = 10.59$), lead ions react with calcium edetate *in vivo* to form a lead chelate that is excreted in the urine.

Pharmacodynamics

On absorption, calcium edetate forms complexes not only with lead but also with zinc, an essential trace metal. During the course of calcium edetate treatment, serum zinc levels may decline to approximately 60–70% of pretreatment values, and urinary zinc excretion may increase approximately 5- to 20-fold [3–6]. This increase may be associated with partial inhibition of zinc metalloenzymes (e.g., alkaline phosphatase). These indices of zinc status return to normal within a few days of cessation of calcium edetate treatment; their clinical significance is uncertain. Calcium edetate exerts no significant pharmacodynamic effects on cardiovascular, hepatic, or renal function.

Pharmacokinetics

Calcium edetate may be administered by either intramuscular injection or intravenous infusion. Oral absorption is poor, and oral administration is not recommended because it may increase

absorption of lead that may be present in the intestinal tract. The volume of distribution is 0.19 L/kg, consistent with distribution in extracellular water [7]. The serum elimination half-life is approximately 2 h in subjects with normal renal function. Calcium edetate is excreted unchanged in the urine, predominantly through glomerular filtration. Some data indicate that relatively greater metal excretion is achieved when the total daily dose is administered by continuous infusion over all or most of the day, as opposed to short-term infusion over 1 h [8, 9] (Grade III evidence). Renal clearance of calcium edetate and the mobilization of lead into the urine occur more slowly in patients with renal insufficiency [7, 10].

Contraindications and Precautions

Because calcium edetate and the metals it mobilizes are excreted in the urine, caution should be exercised in administering the drug to patients with renal insufficiency. In patients with moderate renal insufficiency, a reduction in dose proportionate to the deficit in creatinine clearance is appropriate. Some case reports suggest that calcium edetate can be used in conjunction with peritoneal dialysis, hemodialysis, or hemofiltration to enhance lead decorporation in lead-poisoned patients with renal failure [11–14]. A recommended protocol is to administer 1 g of calcium edetate in 250 mL normal saline intravenously over 1 h, followed immediately by 4 h of hemodialysis using a high flux dialysis membrane, such as the F160 [15] (Grade III evidence).

Calcium edetate was teratogenic when administered to pregnant rats at a dose of 4 mmol/m²/day (comparable to a therapeutic adult human dose of approximately 40 mg/kg/day) [16]. This teratogenicity may have been a consequence of zinc depletion, because the administration of a zinc chelate of EDTA was not teratogenic. Calcium edetate has diminished the adverse reproductive effects of lead in pregnant experimental animals [17] and in two isolated reports has been used to treat lead poisoning in the late stages of human gestation without apparent adverse effect [18, 19]. Calcium edetate is rated pregnancy

category B (pregnancy category means that animal reproduction studies have failed to demonstrate a risk to the fetus and there are no adequate and well-controlled studies in pregnant women OR animal studies have shown an adverse effect, but adequate and well-controlled studies in pregnant women have failed to demonstrate a risk to the fetus in any trimester) by the US Food and Drug Administration. If its use in pregnancy is necessary, maternal supplementation with zinc (e.g., 25 mg zinc sulfate orally during chelation and for one additional week) is advisable based on moderate evidence of the salutary effects of treatment of zinc deficiency during pregnancy [20] (Grade III evidence).

Adverse Effects

Calcium edetate generally is well tolerated, and adverse effects are rare. The drug has been associated with nephrotoxic damage to the proximal tubule in humans and animals, usually after administration of high or protracted doses [21, 22]. Moel and Kumar [23] reported four pediatric cases of oliguric acute renal failure among 207 courses of lead chelation that consisted of 5 days of combined treatment with calcium edetate, 50 mg/kg/day, and dimercaprol, 18 mg/kg/day. The oliguria developed 1–2 days after chelation was discontinued and lasted 2–4 days. Elevations in serum creatinine (3.9–8.4 mg/dL) normalized after 11–22 days. Although such nephrotoxicity from calcium edetate is uncommon, it is appropriate to monitor renal function (urinalysis, blood urea nitrogen, serum creatinine) at the onset of treatment and every 24–48 h during therapy. To reduce the risk of nephrotoxicity, a course of calcium edetate treatment should not exceed 5 consecutive days, and repeat courses should be separated by at least a 2-day interval. Maintaining urine output of approximately 1–2 mL/kg may optimize lead elimination and diminish the risk of nephrotoxicity, but care must be taken to avoid fluid overload in patients with lead encephalopathy and cerebral edema. Calcium edetate has been associated with mild reversible increases in hepatic transaminases, which are of minimal or no clinical significance [5].

Administration

Continuous intravenous infusion is the preferred route of calcium edetate administration. The drug should be diluted to a concentration of 2–4 mg/mL in normal saline or 5% dextrose. In adults with severe lead poisoning, the recommended dose is 2–4 g (30–50 mg/kg) intravenously per 24 h, as a continuous infusion. The pediatric dose is 1000–1500 mg/m²/24 h as a continuous intravenous infusion. To diminish the risk of nephrotoxicity, a course of treatment should not exceed 5 consecutive days.

Although intravenous administration is preferable, the daily dose of calcium edetate also can be administered by deep intramuscular injection in divided doses spaced 8–12 h apart. To minimize pain at the injection site, lidocaine can be added to the calcium edetate injection solution to achieve a final lidocaine concentration in the injectate of 5 mg/mL (0.5%). Calcium Disodium Versenate (edetate calcium disodium injection, USP) is supplied as 5-mL ampules containing 200 mg/mL of calcium edetate (1 g per ampule). Lower cost pharmaceutical-grade calcium disodium edetate bulk powder may also be obtained by hospital pharmacies for preparation of compounded intravenous solutions.

Cyanide exposure can cause rapid death. The most common cause of cyanide toxicity is inhaled cyanide (hydrogen cyanide) from structure fires [1, 2]. While fortunately less common, the most interesting cause of cyanide toxicity come from suicidal and homicidal acts. There are as many deaths each year in the United States as from cardiac glycosides, beta blockers alone, or organophosphates [3]. The largest threat of cyanide toxicity is actually the result of terrorism and war [4]. Recent events have highlighted the need for preparedness against possible chemical terrorist attacks. Cyanide also creates an occupational hazard in industries such as electroplating, metal extraction, pest control, and oil field work. Several treatments are available to treat cyanide toxicity, and clinical practice guidelines are available [1, 5, 6]. The availability of antidotal therapy also is subject to impact from both market and regulatory forces [7, 8].

In the United States, the two most common antidotes used are hydroxocobalamin and sodium nitrite/sodium thiosulfate (Nithiodote, Hope Pharmaceuticals) [9]. In Europe, both hydroxocobalamin and 4-dimethylaminophenol (4-DMAP) are used. Dicobalt edetate is available in Germany but does not find widespread use elsewhere [10]. The cyanide antidote kit (Lilly Cyanide Kit, Eli Lilly, Indianapolis, IN) contains amyl nitrite, sodium nitrite, and sodium thiosulfate and was produced for over 50 years; however, this is no longer manufactured [11]. Guidelines in Australia, Europe, and the United Kingdom vary. However, most recommend hydroxocobalamin as

the first-line agent for the management of cyanide toxicity [5, 6].

Cyanide antidotes are administered to patients suspected of suffering cyanide toxicity. This suspicion is most often based on the triad of altered mental, lactic acidosis, and hypotension, in concert with a clinical suspicion of cyanide exposure. Because bedside or field testing for cyanide is not available, the antidotes are often empirically administered. In patients who are not critically ill but likely intoxicated with cyanide, administration

of the antidote may reduce the incidence of persistent neurological effects [12, 13].

Cyanide toxicity is discussed in detail in ► Chap. 97, “Cyanide: Hydrogen Cyanide, Inorganic Cyanide Salts, and Nitriles.”

Pharmacodynamics

Cyanide antidotes work by different mechanisms (Tables 1, 2, and 3).

Table 1 Cyanide-binding antidotes

Antidote	Typical dose	Mechanism of action	Adverse effects
Dicobalt edetate (Kelocyanor)	300 mg IV	Chelation of cyanide. Dicobalt edetate complexes with cyanide forming cobalt cyanide, removing cyanide from the circulation and reducing toxicity	Severe hypotension, cardiac arrhythmias, convulsions. Gross edema after treatment with dicobalt edetate also has been reported. These effects are most common when infused in the absence of cyanide. Intravenous glucose may mitigate some of these adverse effects
Hydroxocobalamin	5–15 g IV	Chelation of cyanide. Cobalt complexes with cyanide to form cyanocobalamin (vitamin B ₁₂)	Minimal, transient reddish discoloration of the skin, mucous membranes, and urine, producing a increase in blood pressure Allergic reactions have been noted

IV, intravenously

Table 2 Methemoglobin inducer antidotes

Antidote	Typical dose	Mechanism of action	Adverse effects
4Dimethylaminophenol (4-DMAP)	5 mL of 5% 4-DMAP solution (250 mg or 3–4 mg/kg) IV for 1 min	Generates a methemoglobin concentration of 30–50% within a few minutes at these doses	Poor dose–response curve reproducibility. Hemolysis has been shown at therapeutic doses
Amyl nitrite pearls		Methemoglobin formation, which promotes a concentration-dependent movement of cyanide out of mitochondria	Methemoglobinemia and hypotension
Sodium nitrite	10 mL (30 mg/mL) IV	Methemoglobin formation, which promotes movement of cyanide out of mitochondria. Clinical effects are observed before significant levels of methemoglobinemia, however, suggesting an alternate mode of action	The mean of the peak amount of methemoglobin concentrations is 10% after administration of 300 mg of sodium nitrite. Hypotension may occur

Table 3 Sulfur donors – sodium thiosulfate

	Typical dose	Mechanism of action	Adverse effects
Sodium thiosulfate	50 mL (250 mg/mL) IV or 12.5 g/50 mL	Administer thiosulfate IV. Thiosulfate reacts with cyanide ion to form thiocyanate. Thiocyanate is nearly nontoxic and rapidly excreted renally	High thiocyanate concentrations (>10 mg/dL) have been associated with vomiting, psychosis, arthralgias, and myalgia

Cyanide Binders – Hydroxocobalamin and Dicobalt Edetate

Hydroxocobalamin is a precursor to cyanocobalamin (Vitamin B12) [14]. It is designed with a cobalt atom that binds cyanide, forming cyanocobalamin. This nontoxic product is excreted in the urine (Fig. 1). Hydroxocobalamin does not form methemoglobin; it binds directly to cyanide (Fig. 2). It is a single drug and is relatively safe. The elimination half-life is 24–48 h. In clinical and preclinical studies, it has shown to be effective after cyanide-induced apnea, hypotension, and cardiac arrest [15–17].

Dicobalt edetate is also an intravenous chelator of cyanide designed around a cobalt moiety [5]. It has a rapid onset of effect but has many adverse effects described below.

Methemoglobin Inducers

Several antidotes use methemoglobin induction to detoxify cyanide. Hemoglobin contains ferrous iron (Fe^{2+}) which is oxidized to ferric iron (Fe^{3+}) in methemoglobin by sodium nitrite, amyl nitrite, 4-DMAP, and other similar drugs [13]. Cyanide has a greater affinity for methemoglobin than hemoglobin. The resultant cyanomethemoglobin is less toxic than cyanohemoglobin. Significant methemoglobinemia occurs within about 30 min of administration of sodium nitrite with significant clinical

Fig. 1 Chemical structure of hydroxocobalamin

Fig. 2 Conversion of hydroxocobalamin and cyanocobalamin

benefit occurring within a few minutes of administration [18]. This timing suggests another, less well understood, effect of methemoglobin inducers may also contribute to overall therapeutic benefit.

Fig. 3 Chemical structure of sodium thiosulfate

Sulfur Donors – Sodium Thiosulfate

Sodium thiosulfate (Fig. 3) is thought to work primarily by sulfur donation to cyanide, producing the less toxic thiocyanate, which is renally eliminated [19]. This approach exploits rhodanese and similar innate ubiquitous enzymes, which serve to facilitate the detoxification of cyanide to thiocyanate.

Administration

Several antidotes are available for use in cyanide toxicity. In the United States, hydroxocobalamin is the most common agent stocked and used [8, 16, 20]. Sodium nitrite with sodium thiosulfate is also available. In the United Kingdom, dicobalt edetate is available and in Germany, 4-DMAP is used [6]. In most cases, administration of the antidote is done empirically based on initial laboratory testing (e.g., serum lactate) and clinical exam. In almost all cases, it is not appropriate to wait for the results of a cyanide level before beginning antidotal therapy (Level of Evidence (LOE) III). The overall treatment of cyanide poisoning is discussed more thoroughly in ► Chap. 97, “Cyanide: Hydrogen Cyanide, Inorganic Cyanide Salts, and Nitriles.”

Supplemental oxygen therapy must be initiated prior to administering cyanide antidotes (LOE II-2). Oxygen therapy alone is an important addition to the management of cyanide toxicity, and for mild or moderate cases of cyanide toxicity, oxygen alone may be sufficient [21]. This approach has not been validated in clinical studies but should be considered in circumstances involving many casualties or when availability of cyanide antidotes is limited (LOE II-3).

Hydroxocobalamin

Hydroxocobalamin is administered as 5 g over 30 min (70 mg/kg in a child) [1] (LOE I-1). If no

effect is observed after 5–15 min, an additional dose of 5 g may be given, up to a total dose of 15 g if needed. However, faster infusion rates may be used if needed in cases of cardiac arrest or severe clinical distress [17] (LOE-II). Hydroxocobalamin is contraindicated in patients allergic to vitamin B₁₂. Sodium thiosulfate may also be administered, though there is no clear additive benefit [10, 19] (LOE II-3). If both drugs are given, they should be infused separately [22].

Sodium Nitrite and Sodium Thiosulfate

These drugs are commonly administered together and are packaged together (Nithiodote, Hope Pharmaceuticals). The traditional cyanide antidote kit (amyl nitrite, sodium nitrite, sodium thiosulfate) is no longer manufactured. The dose for sodium nitrite is 300 mg (10 mg/kg) intravenously over several minutes. Methemoglobinemia of 15–20% is the goal, and the drug produces minimal adverse effects at usual doses [5]. A lower dose is required for children less than 25 kg and in anemic patients. The dose may be repeated in 30–60 min if an acceptable improvement in clinical effects is not detected. Use of sodium nitrite as a methemoglobinemia inducer is not preferred in patients with carbon monoxide toxicity; however, it is not contraindicated, and clinical judgment and experience should guide the decision [18, 19] (LOE II-3).

Sodium thiosulfate is a common sulfur donor. This drug converts cyanide into thiocyanate by donating sulfur and with the facilitation of rhodanese and other similar innate enzymes [23]. Thiocyanate is then cleared renally. The usual dose is 12.5 g (50 mL of 25% solution) intravenously; however, other formulations for intramuscular dosing have been studied and found to be effective. In children, the proper dose is 1 mL/kg intravenously (max of 12.5 g) [10]. Sodium thiosulfate dosing may be repeated in 30–60 min if adequate improvement is not observed. Sodium nitrite and sodium thiosulfate together may have a synergistic effect [13].

Amyl Nitrite

Amyl nitrite is a methemoglobin-inducing inhalant [24]. It was included in the Lilly Cyanide Antidote Kit, which is no longer manufactured. The ampule is crushed and the patient inhales the contents for 30 s. It can be inhaled through the nose or through the endotracheal tube. Amyl nitrite has traditionally been used as a prehospital therapy and as a temporizing measure prior to administration of parenteral antidotes. However, recent research suggests it may be effective alone for mild to moderate cyanide toxicity [25] (LOE II-2).

Dicobalt Edetate

Dicobalt edetate is administered as 300 mg (20 mL of 1.5% solution) intravenously over 1–5 min [5]. This dose is repeated if no improvement is observed after 5 min. Because of the potential for severe adverse effects, this antidote should only be administered when the diagnosis of cyanide toxicity is certain and other therapies are either unavailable or ineffective [5]. Co-administration of glucose (50 mL of 50% solution for adults) may help reduce some of the potential adverse effects (LOE II-2).

Dimethylaminophenol (4-DMAP)

Dimethylaminophenol is administered as 5 mL of 5% solution (250 mg) intravenously over 1 min [10, 26]. For children, the drug is administered intravenously at a dose of 3–4 mg/kg. 4-DMAP is discussed in detail in ► Chap. 144, “4-Dimethylamino Phenol.”

Hyperbaric Oxygen

In most published human reports, hyperbaric oxygen is offered after a combination of other therapeutic modalities, including antidote administration [22, 24]. Based on case reports and

preclinical data, the effectiveness of hyperbaric oxygen for treating cyanide toxicity remains controversial [27–29].

Future

Several novel cyanide antidotes are currently being evaluated. Nitrocobinamide is a small-volume antidote that contains cobalt in a formulation similar to hydroxocobalamin [30, 31]. One mole of nitrocobinamide can bind two moles of cyanide and has fewer side effects than hydroxocobalamin (Fig. 1). It has been studied in several animal species and appears effective for severe cyanide toxicity [30, 32, 33] (LOE I). Sulfanegen is another promising antidote that can be delivered intramuscularly in a small volume [34]. It is a prodrug for 3-mercaptopyruvic acid (3-MP) and detoxifies cyanide through its actions as a sulfur donor. Several studies have reported efficacy over several animal species and preclinical models [9]. Parenteral DMTS (dimethylsulfide) is a potential antidote for treating cyanide toxicity. It also works through sulfur donation (Fig. 4).

Adverse Effects

While antidotes are effective for the treatment of cyanide toxicity, all have some adverse effects. Hydroxocobalamin has the fewest serious adverse effects. New antidotes such as nitrocobinamide have even fewer associated adverse effects [33]. Knowledge of the adverse event profile prior to antidote administration may help guide the choice of best antidote selection and also may mitigate these effects in the complex, critically ill cyanide-toxic patient.

Hydroxocobalamin

Hydroxocobalamin is safe and has been approved for use in the United States since 2006 [10]. Adverse effects include a transient red

Fig. 4 Chemical structure of cobinamide

color of urine, tears, and skin and bright red blood [35, 36]. This color may be present for 2–3 days. The color change may affect results of colorimetric, spectrophotometric, and co-oximetric assays. The interference with co-oximetry may complicate, or render useless, measurement of carboxyhemoglobin in patients retrieved from structure fires. In addition, other blood tests that may be affected include lactate, alanine aminotransferase, aspartate aminotransferase, creatinine, bilirubin, and magnesium. Urine test results may also be affected. Blood color changes may also interfere with alerts on dialysis machines [37]. Elevated blood pressure occurs frequently with hydroxocobalamin administration and rare cases of anaphylaxis have also been reported [38].

Sodium Nitrite and Sodium Thiosulfate

The FDA placed a Black Box warning on sodium nitrite. Sodium nitrite produces methemoglobinemia of approximately 10% within 30 min of administration [39]. Higher levels of methemoglobinemia can be produced; however, this may also cause respiratory distress and hypoxia. In anemic patients (hemoglobin <14 g/dL), appropriate doses per weight of sodium nitrite should be used, up to a maximum dose of 10 mL

[40]. Hypotension and tachycardia may also occur and are typically transient [40]. Hemolysis rarely occurs and patients with G6PD deficiency are at greatest risk. The precise risk of hemolysis is unknown. Theoretically, inducing methemoglobinemia in a patient with an elevated carboxyhemoglobin level is potentially dangerous and some have recommended administering sodium thiosulfate alone in patients retrieved from structure fires. However, sodium nitrite is an effective and rapidly acting antidote for cyanide toxicity, and its administration should be given consideration if hydroxocobalamin is not available.

Sodium thiosulfate has few adverse effects. It detoxifies cyanide by converting it to thiocyanate. High levels of thiocyanate (>10 mg/dL) may cause arthralgias, psychosis, and vomiting [7]. Extracorporeal methods (e.g., hemodialysis) of thiocyanate removal may be necessary in patients with renal insufficiency or failure.

Dicobalt Edetate

The current recommended antidote for clinically severe cyanide toxicity in Australia and the United Kingdom is dicobalt edetate [5]. Significant adverse effects are associated with the use of this drug (see Table 150–1), many of which are

life threatening. These effects include seizures, anaphylaxis, dysrhythmia, and hypotension. Therefore, this antidote should be administered only when the diagnosis of cyanide poisoning is certain and other, safer, alternatives are not available. Administration of glucose may mitigate some of these adverse effects (LOE III).

4-Dimethylaminophenol

In Germany, 4-dimethylaminophenol (4-DMAP) is used as a methemoglobin generator in cyanide-poisoned patients because of its rapid onset of action within a few minutes of injection [5]. The adverse effect of methemoglobin formation is greater with 4-DMAP compared to sodium nitrite. It has poor dose–response curve reproducibility. Hemolysis as a result of 4-DMAP therapy has been reported both in overdose and following proper therapeutic doses [41]. Nephrotoxicity and reticulosis have been reported [41]. Methylene blue is often needed to reverse excessive methemoglobin caused by 4-DMAP, which adds additional risk as methylene blue may also increase cyanide release in cyanide-poisoned patients [42].

Special Populations

For pediatric patients sodium thiosulfate is safe to use in weight-based dose. Neonates and infants are more susceptible to severe methemoglobinemia after sodium nitrite. For children, administer the weight-based dose:

- Sodium nitrite – 0.2 mL/kg of a 3% solution (6 mg/kg or 6–8 mL/m² BSA) of sodium nitrite at the rate of 2.5–5 mL/min not to exceed 10 mL (300 mg)
- Sodium thiosulfate – 1 mL/kg of body weight using a 25% solution (250 mg/kg or approximately 30–40 mL/m² of BSA) not to exceed 50 mL (12.5 g) total dose immediately following administration of sodium nitrite

For pediatric patients, the dose safety of hydroxocobalamin has not been determined; however, reports have been published that recommend it and the dose used is 70 mg/kg parenterally [43] (LOE III).

For pregnant patients, the data on cyanide antidotes is limited. Sodium thiosulfate and sodium nitrite are Pregnancy Category C (<http://www.hopepharm.com/prescribing/>- package insert). Hydroxocobalamin is also assigned Pregnancy Category C. Use these antidotes with benefit outweighing the possible risk of their use. Since cyanide toxicity can be lethal and severely damaging to the fetus, and antidote use can be lifesaving, often the benefit outweighs the risk (LOE III).

Cyproheptadine is a first-generation piperidine antihistamine that is an antagonist at H₁ receptors and some serotonin receptor subtypes [1, 2]. Labeled uses of cyproheptadine include those related to its antihistaminic properties, such as allergic rhinitis and urticaria. Off-label, it has been used for its antiserotonergic properties including appetite stimulation in chronic disease, migraine prophylaxis, treatment of pruritus and spasticity associated with spinal cord injury, and management of serotonin syndromes [2–4]. Its use as an adjuvant in the treatment of baclofen withdrawal has also been reported [5–8]. The focus of this chapter is the use of cyproheptadine for the management of serotonin syndrome.

History

In the USA, a patent for cyproheptadine was issued to Merck & Co. in 1961. The drug was originally marketed under the brand name “Periactin[®],” which is no longer available in the USA, although cyproheptadine can be obtained in both tablet and liquid forms from generic manufacturers [9, 10].

Physicochemical Properties

The empirical formula of the anhydrous salt is C₂₁H₂₁N·HCl. The sesquihydrate form of the drug has a molecular weight of 350.89 g/mol

[11]. Cyproheptadine hydrochloride USP is a white to slightly yellow crystalline solid which is freely soluble in methanol, soluble in chloroform, slightly soluble in water, sparingly soluble in ethanol, and nearly insoluble in ether [11, 12].

Pharmacodynamics

Current human and animal studies suggest 5-HT_{2A} receptors are responsible for the more severe and life-threatening effects of serotonin syndromes, such as hyperthermia and hypertonicity or a hyperserotonergic state. 5-HT_{1A} receptors are probably responsible for less-severe effects such as hyperactivity and anxiety [4]. The nonspecific 5-HT₂ antagonist activity of cyproheptadine provides the basis for the suggestion that it may be clinically useful in managing states associated with serotonin excess.

When the serotonin precursor 5-hydroxy-L-tryptophan (5-HTP) is administered to rats in which monoamine oxidase activity is blocked with clorgyline, a hyperserotonergic state resulting in serotonin toxicity (i.e., serotonin syndrome) is induced. This model allows for the study of the efficacy of various serotonin antagonists, administered either before or after induction of serotonin syndrome. Nisijima used this model of serotonin syndrome in a rat study in which various drugs were given intraperitoneally (IP) prior to serotonin syndrome induction in order to evaluate their efficacy in preventing life-threatening effects [13]. Serotonergic effects attributed to 5-HT_{1A} agonism included tremor, forepaw treading, and Straub tail while those attributed to 5-HT_{2A} included increased norepinephrine levels in the anterior hypothalamus, hyperthermia, hypertension, and shock. The 5-HT_{2A}, but not the 5-HT_{1A}, effects were associated with death. Only the drugs with 5-HT_{2A} antagonist effects prevented death. And, in these cases, death was prevented only when sufficiently high doses of less-potent 5-HT_{2A} drugs were given. The 5-HT_{2A}-specific antagonists pipamperone and ritanserin consistently prevented hypothalamic increases in norepinephrine, hyperthermia, and death while 5-HT_{1A} antagonists did not; the authors concluded the most

serious serotonin effects appeared to be mediated by 5-HT_{2A} receptors. Therefore, it was reasoned that successful treatment of more serious toxicity required 5-HT_{2A}-antagonist drugs. Cyproheptadine, a less specific 5-HT antagonist drug than pipamperone or ritanserin, inhibits 5-HT_{2A} receptors. In this study, a 10 mg/kg IP dose of cyproheptadine was successful in preventing hyperthermic death in rats, whereas a smaller 5 mg/kg IP dose was not.

Using the same model of serotonin syndrome, Ma administered cyproheptadine after serotonin syndrome was induced in rats [14]. Cyproheptadine, when given as a 10 mg/kg IP dose, prevented hyperthermic death in rats with serotonin syndrome when given 15 min after induction of toxicity, but before the onset of hyperthermia. In contrast, death was slowed, but not prevented, when cyproheptadine was given 60 min after induction, by which time severe hyperthermia had already developed.

Zhang administered 10 mg/kg IP cyproheptadine to rats after serotonin syndromes were induced with 5-HTP and clorgyline and noted that the efflux of serotonin from the hypothalamus and cortex were attenuated, confirming prior work demonstrating the ability of cyproheptadine to antagonize 5-HT_{2A} receptors is the most likely mechanism for effectiveness in managing serotonin excess [15]. The authors theorized two separate but related mechanisms led to serotonin excess in significant cases: the initial augmentation caused by increased synthesis, and decreased breakdown of serotonin, followed by secondary activation of a 5-HT and NMDA neural circuit, amplifying the increase in 5-HT in the central nervous system. For activation, the secondary mechanism required the primary increase in serotonin first reach a threshold level.

Rats given doses of citalopram sufficient to induce seizures and death were protected by 17.1 mg/kg cyproheptadine or by 1.77 mg/kg diazepam IP [16].

A PET scan done in 2 patients given either 4 mg or 6 mg of cyproheptadine 3 times daily for 6 days showed that 5-HT₂ receptors in the prefrontal cortex are 85% blocked at a 12 mg/day dose and 95% blocked at 18 mg/day [17].

The animal studies reviewed above are of good quality, with appropriate controls and effective dose-finding. (Level of evidence [LOE] II-1) Human research in serotonin syndrome management is based entirely on case reports and reviews. (LOE Grade III) The pharmacodynamics and pharmacokinetics may differ between rodents and humans [4, 18, 19]. The timing with regard to onset of serotonin syndrome and administration of antidote is rarely, if ever, as ideal in humans as in rodent research. Additionally, serotonin syndrome is not always easily diagnosed with certainty and in most instances resolves quickly. For these reasons, it is difficult to assess the efficacy of any antidote given to manage serotonin syndrome. Therefore, while it is logical that administration of cyproheptadine to humans may alleviate or entirely resolve the effects associated with serotonin syndrome, it has not been demonstrated whether this occurs reliably at the doses currently administered to humans.

Pharmacokinetics

The pharmacokinetic profile of cyproheptadine in humans is not well studied. The drug is well absorbed after oral administration, but <15% of an 8 mg sublingual dose is absorbed. The peak level of glucuronidase-incubated cyproheptadine after oral ingestion of 8 mg occurred at 4 h [20]. Cyproheptadine distributes so rapidly into tissues that neither the parent compound nor the desmethylycyproheptadine metabolite is detected in plasma well under 2 h postingestion. Cyproheptadine is almost entirely metabolized, followed by renal metabolite elimination, mostly as glucuronide and sulfate conjugates. When radioactivity of any compound containing cyproheptadine in the plasma was measured after the administration of radioactive cyproheptadine, the peak radiation measurement occurred in 6–9 h after a 5 mg oral dose of solution [18]. Cyproheptadine undergoes hydroxylation of the aromatic ring, then glucuronidation, N-demethylation, and heterocyclic ring oxidation [19]. Metabolic studies indicate that $\geq 60\%$ of conjugates are glucuronides, with approximately 10% as sulfates

[18]. Roughly two thirds of a cyproheptadine dose is eliminated as metabolites in the urine, with approximately 25% eliminated in feces [18]. Predictably, elimination of metabolites is slowed in renal dysfunction [11].

Contraindications

Contraindications to cyproheptadine use include known hypersensitivity to the drug and circumstances in which anticholinergic effects would be significantly disadvantageous (e.g., pyloroduodenal obstruction, urinary obstruction, angle-closure glaucoma, and stenosing peptic ulcer) [2, 11]. Careful risk-benefit analysis should take place before use of cyproheptadine in patients with benign prostatic hypertrophy, and if it is to be used in young children or the elderly, who are more likely to have adverse effects when given anticholinergic medications [11, 12].

Concomitant use of cyproheptadine and monoamine oxidase inhibitors (MAOIs) is listed as being contraindicated in the cyproheptadine package insert. The listed concerns are an increase in anticholinergic effects, decrease in efficacy of MAOI antidepressants, and the hypothetical potential for toxicity. These concerns are based on a single unconvincing case report in which a patient developed irritability and visual hallucinations 2 months after beginning cyproheptadine therapy for phenelzine-induced anorgasmia [21, 22]. As cyproheptadine is expected to decrease serotonergic excess-related toxicity caused by the combined use of MAOIs with other serotonergic agents, this reported contraindication should probably not be a deterrent to using cyproheptadine to manage serotonin toxicity associated with MAOIs.

Adverse Effects

Most information about the adverse effects of cyproheptadine is derived from therapeutic use. Cyproheptadine is associated with increase in appetite and associated weight gain; sedation; anticholinergic effects (dry mouth, glaucoma,

urinary retention); and sometimes central nervous system stimulation (agitation, confusion, and visual hallucinations) [23].

Adverse effects of cyproheptadine are more likely with higher dosing, but the occurrence and severity of these effects appears to show individual variability [24, 25]. Sedation is the most common effect consistently reported [26–30] and more likely with higher doses. In a study evaluating the use of cyproheptadine given for blepharospasm, 8–24 mg daily in divided doses caused drowsiness and dry mouth [24]. The effect of increased appetite is often used for therapeutic intervention in patients requiring weight gain [27, 28]. Dizziness and sedation were reported in adult cancer patients given cyproheptadine 8 mg three times daily for anorexia or cachexia [25]. In addition to the more common adverse effects of sedation and increased appetite, some less common reported effects include agitation, confusion [28], psychosis [31], and acute hepatitis with prolonged anicteric cholestasis [32].

The therapeutic dose of cyproheptadine for children is 2 mg 2–3 times daily in 2- to 6-year-olds (maximum 12 mg/day) to 4 mg 3 times daily in 7- to 14-year-olds (maximum 16 mg/day) [2]. In pediatric overdoses, cyproheptadine causes anticholinergic effects similar to other first-generation antihistamines. In one case report of a 4-year-old child who ingested 22.5 mg, disorientation, ataxia, irritability, athetosis, mydriasis, tachycardia, hyperthermia to 38.8 °C, meaningless speech, and intermittent crying spells occurred, all lasting less than a day [33]. A 7-year-old hemodialysis patient taking cyproheptadine 4 mg nightly to increase his appetite was accidentally raised to 8 mg twice daily. This accidental overdose occurred 2 days after triprolidine/pseudoephedrine and ampicillin were added for an ear infection. After the accidental increase of cyproheptadine, the child developed hallucinations, tremors, and hearing difficulty that did not resolve completely for days after discontinuation [34].

Similar, but less severe, effects were reported when the drug was used therapeutically in children. The most common adverse effects associated with weeks-long use of cyproheptadine at a

dose of 0.04–0.62 mg/kg/day (median 0.19 mg/kg/d) for dyspepsia in children were somnolence (16%), irritability and behavioral changes (6%), increased appetite and weight gain (5%), and abdominal pain (2%) [25]. Anticholinergic toxicity was reported in a 9-year-old prescribed cyproheptadine 4 mg twice daily for migraine headaches. He developed “mean” behavior, then agitation, confusion, and hallucinations with tachycardia [35]. Headache and vertigo may be related to use [29, 30]. One case reported violent aggression in a 5-year-old boy taking 6 mg/day for months. The child was given cyproheptadine and levothyroxine to stimulate growth, then became more agitated and aggressive after cyproheptadine was added. The effects began to decrease within a few days of discontinuation of cyproheptadine and significantly decreased in just over a month. The levothyroxine was initiated 3 months prior to the cyproheptadine and discontinued more than a week after the cyproheptadine was discontinued, therefore the levothyroxine likely did not play a significant role. Also, the thyroid hormone levels were normal throughout. One additional confounder is a change in psychotherapy 2 weeks prior to the cyproheptadine discontinuation. The treatment team believed the temporal association favored cyproheptadine as the most likely cause of enhanced aggression in this child [36].

With repeated therapeutic dosing, cyproheptadine causes significant sedation and increase in appetite, even in doses as small as 4 mg in adults. Dry mouth, irritability, confusion, nausea, and abdominal pain have also been reported. Other effects that are less common but may be related to therapeutic use include headache, vertigo, violent aggression, and acute hepatitis with anicteric cholestasis. Sedation is more severe initially and with increasing doses. In cases of pediatric overdose, tachycardia, mydriasis, ataxia, disorientation, hallucinations, athetosis, and hyperthermia have been reported, as with overdoses of other antihistamines.

When cyproheptadine is used for the management of serotonin syndrome, mydriasis [37], blurry vision [37], and urinary retention [38] have been reported in adults. Interestingly, sedation has not been reported as an adverse effect in

this context. However, it may be difficult to observe sedation in patients with serotonin syndromes treated with cyproheptadine. Compared with the effects of the serotonin syndrome, minor to moderate sedation from cyproheptadine would likely go unnoticed. Additionally, other sedatives are often given to patients with serotonin syndrome, so any observed sedation could be due to the other sedatives given or the combination of cyproheptadine with the other sedatives. Any sedation noted would either be considered beneficial or possibly not be attributed to the cyproheptadine, making it unlikely most case reports and studies involving serotonin excess would mention sedation due to cyproheptadine.

High doses of cyproheptadine are used for the management of serotonin syndrome, making adverse effects more likely. However, the clinical significance of the adverse effects is questionable. The potential for anticholinergic effects is worth consideration in the subset of patients previously mentioned (e.g., pyloroduodenal obstruction, urinary obstruction, angle-closure glaucoma, and stenosing peptic ulcer). However, this does not mean the use of cyproheptadine for serotonin syndrome is contraindicated in these patients.

Treatment

The dosing of cyproheptadine for treatment of allergic conditions is typically 4 mg three times daily, increased as needed, up to 0.5 mg/kg/day, to a maximum dose of 32 mg/day. However, dosing for off-label indications can begin with doses as low as 2 mg every 12 h [39].

The best dosing regimen of cyproheptadine for the management of serotonin syndromes has not been formally studied or determined.

Two reviews recommend consideration of an initial dose of 12 mg, followed by 2 mg every 2 h until resolution of the effects of serotonergic excess, followed by 8 mg every 6 h for maintenance. These reviews did not specify whether, when, or how long maintenance dosing is recommended [3, 40]. In the original source review [3], it appears this recommendation is based on a combination of typical maximum

daily dosing for therapeutic use of cyproheptadine and a brief account of research involving positron emission tomography (PET) scans in two adult male volunteers. In this study, the researchers evaluated the antagonistic effect of two different doses of cyproheptadine on 5-HT_{2A} receptors in the prefrontal cortex using PET scan. The subjects took cyproheptadine (either 4 mg or 6 mg) three times daily for 6 days. Scan results were compared before and after 6 days of cyproheptadine. After 6 days of cyproheptadine use, the 4 mg dose (12 mg/day) blocked 85% of 5-HT_{2A} receptors, while the 6 mg dose (18 mg/day) blocked more than 95% of these receptors [17]. It is unclear how it was decided to recommend giving 12 mg in one initial dose based on the information provided. While not dangerous, an initial dose of 12 mg for an adult may not be necessary. The level of evidence supporting this dosing regimen is low (LOE III).

In a third review, the authors recommend titrating 4–8 mg doses until clinical improvement is noted, suggesting as much as 16–20 mg may be required. No timeframe for the titration is provided. The authors proposed a pediatric dose of 0.25 mg/kg/day divided into two or three doses [41]. Another author managed a child with serotonin syndrome by first loading with approximately 0.25 mg/kg (the equivalent of 16 mg in an adult), then giving 0.25 mg/kg/day in three divided doses thereafter [42]. The reported justification was that a higher dose was needed to block 5-HT_{2A} receptors more completely and more quickly. The level of evidence supporting this relatively high dosing is still low (LOE III).

Although reviewers suggest that a higher initial dose of 12 mg, followed by 2 mg every 2 h until clinical resolution, with possible maintenance of 8 mg every 6 h is reasonable, many patients have had a good response with only 4–8 mg. Some of these patients received maintenance doses while others did not [38, 43–48]. Once again, all evidence is low (LOE III).

Patients who respond well usually do so within the first hour after cyproheptadine treatment if the dose is sufficient [6, 38, 44, 46, 48, 49] though some required an additional hour or two [45, 47, 50, 51]. With or without therapeutic intervention,

serotonin syndrome usually resolves in hours to days with discontinuation of the offending agent(s) [3, 40, 52]. For those who fail to respond to cyproheptadine within 4 h of initiation, there is little justification for further dosing. Patients will likely recover with discontinuation of serotonergic agents and supportive care alone. For severe cases, aggressive sedation, with or without neuromuscular blockade and intubation, is required.

Which patients may benefit most from cyproheptadine antidotal therapy for serotonin excess is unclear. Based on rodent studies, cyproheptadine is most useful for moderate to severe toxicity when given prior to onset of significant hyperthermia. However, based on human case reports, patients with mild to moderate toxicity appear to derive the greatest benefit. Most cases of apparent cyproheptadine success involve patients who have not suffered seizures and are not severely hyperthermic. As cyproheptadine is only available in oral formulations, it must be administered through a nasogastric or orogastric tube in critically ill patients, and these patients must have a functioning gastrointestinal tract. Use is most reasonable for mild to moderately ill patients. However, use may be considered in more severely intoxicated patients as long as other necessary measures are not delayed. Any use of cyproheptadine in humans for serotonin syndrome is based on low-level evidence (LOE III).

In consideration of the information available to date, it is reasonable to give cyproheptadine 8 mg once, then to give an additional 4 mg in 1–2 h if serotonergic signs do not improve substantially within 2 h. Subsequent doses (4 mg) are indicated if previously resolved clinical effects return (LOE III). If there is no response to a total cyproheptadine dose of 12 mg within the first 4 h, it is unlikely further dosing will add significant benefit, and other therapeutic approaches such as the use of benzodiazepines or propofol are indicated as needed. Further, if there is no response to cyproheptadine, reevaluation of the diagnosis of serotonin syndrome is warranted.

The goal of cyproheptadine therapy is to decrease the effects of serotonin excess

substantially within the first few hours of dosing, enabling a shorter and more comfortable course for the patient, and to reduce the risk of complications that may accompany severe syndromes (see ► Chap. 24, “Serotonin Syndrome”). As with all antidotes, cyproheptadine is not a substitute for good supportive care. Sedation, intubation, aggressive cooling, or other supportive measures should not be delayed while waiting for cyproheptadine to be effective.

Administration

In the USA, cyproheptadine hydrochloride is available for oral use only as 4 mg tablets or 2 mg/5 ml syrup [9, 10]. If the patient is unable to voluntarily take the medication, cyproheptadine syrup or crushed tablets may be administered through a nasogastric tube [3, 41, 42, 45, 53–56].

Pediatrics

Cyproheptadine is given therapeutically to children 2 years of age and older for allergic conditions in doses of 2 mg 2–3 times daily in 2- to 6-year-olds (maximum 12 mg/day) to 4 mg 3 times daily in 7- to 14-year-olds (maximum 16 mg/day). Alternatively, dosing may be based on weight for a total daily dose of 0.25 mg/kg divided [2]. Cyproheptadine was used to manage serotonin syndrome in two cases involving young children. A 2-year-old was given 0.25 mg/kg divided into 3 doses given every 8 h (1 mg loading dose then 1 mg every 8 h) [49]. A 9-year-old was given a larger loading dose of 0.25 mg/kg followed by maintenance doses of 0.25 mg/kg (8 mg then 2.5 mg every 8 h) [42]. It is reasonable to treat children 2 years of age and older with the therapeutic dose 0.083 mg/kg (0.25 mg/kg in 3 divided doses), which is the therapeutic dose for allergic conditions and the dose that successfully managed one pediatric case of serotonin syndrome (LOEIII).

Pregnancy

Cyproheptadine is a Pregnancy Category B drug. The theoretical reason for serotonergic excess and harm is accumulation of serotonin in the estrogen-sensitized myometrium, leading to uterine contractions and decrease in placental blood flow, leading to abortion [57, 58]. Most, but not all, studies of pregnant animals failed to show harm. Limited human data appear to support safety (LOE II-1, II-3, III).

Studies in rabbits, mice, and rats do not reveal maternal fertility issues or fetal harm when the drug is given in doses up to 32 times the maximum recommended human dose orally or subcutaneously. However, rats dosed with 2–50 mg/kg given intraperitoneally exhibited fetal toxicity affecting multiple different organ systems [11, 12]. Weinstein failed to show teratogenic effects in rats given 0.5–5 mg/kg/day doses of cyproheptadine during their 3 weeks of pregnancy [59]. Pfeifer demonstrated the safety and efficacy of cyproheptadine 5 mg/kg doses given to pregnant rats to prevent fetal death after excessive in utero exposure to serotonin induced by the monoamine oxidase inhibitor pargyline.

Doses of 4 - 16 mg/day of cyproheptadine were given to 29 women (31 pregnancies) to prevent abortion. Prior to the study, these women had 2-12 spontaneous abortions. The drug was given “early” in pregnancy through the end of month seven. The birth rates in these women increased from 14% to 90% with 23 normal babies and 4 surviving premature babies, none of whom displayed teratogenic effects. Adverse effects in mothers were minor and included drowsiness, diplopia, and weight gain [60]. Two successful pregnancies were reported in patients with Cushing’s syndrome taking 12–32 mg/day of cyproheptadine. Both were born healthy. One died 4 months later due to gastroenteritis [61, 62].

Warnings about use in neonates and premature babies suggest cyproheptadine is contraindicated. This information can be traced back to package inserts with similar warnings for multiple

anticholinergic drugs including antihistamines [11, 12]. These warnings may be based on concern for greater toxicity in premature babies and neonates with regard to antihistamine and anticholinergic effects including seizures and excessive drowsiness and apnea.

Based on the apparent safety in most animal studies, the apparent efficacy managing serotonin excess induced by a monoamine oxidase inhibitor given in pregnant animals, the efficacy in preventing human abortions in a small study of women used as their own controls, as well as the apparent safety and possibly efficacy in two human case studies involving use in pregnant women with Cushing’s Syndrome, cyproheptadine seems relatively safe in pregnant women in all trimesters. However, human data are limited.

Use in pregnant women with serotonin excess is reasonable when indicated based on the same criteria as in nonpregnant individuals (LOE II-1, II-2 and III).

Dantrolene is a unique, noncentrally acting, nondepolarizing muscle relaxant used primarily to treat malignant hyperthermia associated with inhaled anesthetics. It is also used in the management of chronic muscle spasticity caused by upper neuron disorders such as stroke, spinal cord injury, cerebral palsy, and multiple sclerosis.

History

Snyder and colleagues [1] first described the possible muscle-relaxing properties of dantrolene in 1967, while studying the ability of substituted furans to inhibit hind-limb flexor reflexes in cats. Shortly thereafter, dantrolene was shown to alleviate muscle spasticity effectively in animals [2] and humans [3]. In 1972, Ellis and colleagues [4, 5] showed that dantrolene uncoupled the excitation-contraction process during skeletal muscle stimulation. Because malignant hyperthermia was thought to result from continuous muscle contraction, perhaps through an abnormality in the excitation-contraction coupling mechanism, the compound was tested as a treatment for this condition. In 1982, the first human data were published showing that dantrolene could significantly reduce mortality associated with malignant hyperthermia [6]. Since then, dantrolene has been tried in the treatment of other medical conditions associated with muscle spasm, such as tetanus [7, 8], neuroleptic malignant syndrome [9], lethal catatonia [10], drug-induced rigors [11, 12], black widow spider envenomation

Fig. 1 Chemical structures of dantrolene and, for comparison, hydantoin, nitrofurantoin, and phenytoin

[13], 3,4-methylenedioxymethamphetamine (MDMA, “Ecstasy”) intoxication [14], phenelzine poisoning [15], theophylline poisoning [16], muscle rigidity associated with carbon monoxide poisoning [17], and organophosphate poisoning [18]. Dantrolene protected mice envenomated with *Androctonus australis hector* scorpion venom [19]. It also has been used as a treatment for neurogenic bladder obstruction associated with external urethral sphincter spasm [20] and as a potential treatment for cerebral vasoconstriction [21–23].

By the early 1990s, there was growing evidence that nerve injury may be mediated by elevated intracellular calcium. Dantrolene prevents release of calcium stored in endoplasmic and sarcoplasmic reticula. Recent studies have focused on using dantrolene as a possible neuroprotective agent for treating Alzheimer’s disease [24, 25] and neurotoxicity secondary to subarachnoid hemorrhage [22, 26].

to phenytoin and nitrofurantoin (Fig. 1). Anhydrous dantrolene sodium has a molecular weight of 336 g/mol. Medicinal dantrolene is an orange hemiheptahydrate sodium salt with a molecular weight of 399 g/mol. It is a weak base (pKa 7.5) that is only slightly soluble in water [27, 28]. Dantrolene is available commercially as 25, 50, and 100 mg oral capsules and as 20 mg (Dantrium[®], Revonto[®]) and 250 mg vials (Ryanodex[®]) for intravenous administration (brand names and formulations shown are those for products available in the USA and may be different in other countries). Sodium hydroxide and mannitol are added to the intravenous products to enhance solubility. Ryanodex[®] is formulated as a nanocrystalline suspension instead of as a standard lyophilized powder [29]. It can be reconstituted much faster and delivered in a much smaller total volume than traditional injectable dantrolene [30] (Table 1).

Properties

Dantrolene (1-[[[5-(4 nitrophenyl)-2-furanyl] methylene] amino]-2,4-imidazolidinedione) is a hydantoin derivative with structural similarities

Pharmacodynamics

Dantrolene is a ryanodine receptor antagonist. Ryanodine receptors (RyR) exist on the surface of endoplasmic and sarcoplasmic reticula. They

Table 1 Comparison of injectable forms of dantrolene

Brand name (manufacturer)	Dosage form	Reconstituted dantrolene concentration	Mannitol content per vial (mg)	Vials required for loading dose ^a	Loading dose ^a total volume (mL)	Reconstitution time for loading dose ^a

^aBased on 2.5 mg/kg loading dose for 70 kg adult

exist in three isoforms with varying tissue expression. RyR1 are found primarily in skeletal muscle tissue. RyR2 are expressed primarily within cardiac muscle while RyR3 are expressed primarily in the brain and smooth muscle [31, 32]. RyR are ligand-gated and ligand-modulated. In skeletal muscle, RyR1 are activated by a physical interaction with dihydropyridine receptors. In other tissues RyR1, RyR2, and RyR3 are activated by increases in cytoplasmic calcium concentrations [33, 34]. Dantrolene inhibits RyR1 and RyR3 receptors but not RyR2 receptors. Dantrolene binds to the N-terminus of RyR1 stabilizing it in a closed state thereby preventing the release of calcium from sarcoplasmic reticulum, which in turn prevents activation of troponin C and subsequent interaction of actin and myosin [35, 36]. The relaxation of skeletal muscle allows body heat to be released more efficiently (Fig. 2) [37]. There is growing evidence that dantrolene may also inhibit store-operated calcium channels, the channels that allow intracellular calcium entry so endoplasmic reticula may be replenished [38]. Dantrolene does not affect pretubular steps of skeletal muscle excitation-contraction. It has weak muscle relaxant effects on smooth muscle and only depresses cardiac contractility when used in higher than therapeutic doses [39–41].

Tissue cell and animal research suggests that dantrolene may be beneficial in preventing nerve cell loss in certain neurodegenerative diseases such as Alzheimer’s disease, amyotrophic lateral sclerosis, spinocellular ataxia, and reperfusion injury [31]. A common pathway for injury in each of

these diseases is a triggering event leading to a rise in intracellular calcium within nerve cells. The elevated intracellular calcium then leads to destruction of key intracellular structures, lysosomal autophagy, improper protein folding apoptosis, and eventually neural cell necrosis. Dantrolene’s inhibitory effects on RyR1 and RyR3 in the brain may impart neuroprotective effects.

Pharmacokinetics

Approximately 70% of an oral dose of dantrolene is absorbed in humans. In animals, dantrolene is absorbed primarily in the small intestine [42]. Peak blood concentrations occur 4–8 h after ingestion in healthy human volunteers [43]. Therapeutic blood concentrations are 0.3–0.6 $\mu\text{g/mL}$ (1–1.9 $\mu\text{mol/L}$) for treatment of spasticity [43–45] and 2–3 $\mu\text{g/mL}$ (6.4–9.5 $\mu\text{mol/L}$) for treatment of malignant hyperthermia [46, 47]. When given intravenously to healthy adult volunteers, dantrolene followed a two-compartment distribution model. The initial volume for a 69.5 kg adult was 3.24 L and the final volume was 22.9 L. Distribution from the initial compartment to the final compartment occurs quickly. The intracompartment distribution half-life ($t_{1/2a}$) was 1.6 min [48]. Dantrolene crosses the placenta in humans with a fetal-to-maternal serum concentration ratio of 0.4–0.7 [49, 50].

When distributed, dantrolene is metabolized in the liver by 5-hydroxylation of the hydantoin ring, resulting in 5-hydroxydantrolene (Fig. 3), which is

Fig. 2 Schematic of excitation-contraction coupling in skeletal muscle in relationship to malignant hyperthermia. A somatic motor neuron impulse propagates along the sarcolemmal membrane into the transverse tubule. The impulse activates the dihydropyridine (*DHP*) receptor which in turn physically interacts with ryanodine receptors to cause release of calcium ions from the sarcoplasmic reticulum. Free calcium leads to muscle contraction,

acidosis, and increased body temperature. Dantrolene stabilizes the ryanodine receptor in the closed position thereby preventing abnormal release of calcium from sarcoplasmic reticula (Adapted from Fig. 3, Oliver Bandschapp, Thierry Girard: Malignant hyperthermia, Swiss Med Wkly. 2012;142:w13652. Used with permission from EMH Swiss Medical Publishers, Ltd.)

about half as potent in inhibiting twitch contractions as the parent compound [51]. In children, steady-state concentrations of 5-hydroxydantrolene are 30–50% those of dantrolene [52]. Dantrolene also may undergo reduction of the phenyl nitro group to form aminodantrolene. Aminodantrolene is acetylated further to the pharmacologically inactive reduced aminodantrolene (see Fig. 3) [51].

Approximately, two-thirds of the absorbed dose of dantrolene appears in bile. The remaining one third appears in the urine, with 79% as the 5-hydroxydantrolene metabolite, 17% as the reduced acetylated metabolite, and 4% unchanged [39, 42, 52]. The renal clearance of dantrolene in healthy volunteers is 1.8–7.8 L/h. Dantrolene's serum half-life is 6–9 h in adults with spasticity [39, 45]. The mean half-life of dantrolene in patients with malignant hyperthermia is 12 h

[53]. In children, the half-life is 7–10 h [52, 54]. In neonates, the half-life is 20 h [52].

Pharmacokinetics of Dantrolene

Volume of distribution: two compartment; initial $V_d = 0.047$ L/kg; final $V_d = 0.33$ L/kg

Oral bioavailability: 70%

Time to peak blood levels: 4–8 h

Therapeutic range: 0.1–0.6 $\mu\text{g/mL}$ (spasticity); 2–3 $\mu\text{g/mL}$ (malignant hyperthermia)

Metabolism: extensively metabolized in liver by hydroxylation or acetylation

Route of clearance: 70% biliary, 30% renal

Clearance: 1.8–7.8 L/h

Half-life: healthy adults, 6–9 h; adults with malignant hyperthermia, 12 h; children, 7–10 h; neonates, 20 h

Fig. 3 Metabolic pathway for dantrolene sodium

Special Populations

Pediatric and Geriatric Patients

There is little published dosing experience with dantrolene in neonatal or geriatric populations. Current dosing guidelines apply to children 5 years old and older. It is likely that dantrolene

accumulates in patients with renal, hepatic, or biliary impairment. Dosage reductions should be considered in these patients, especially if the drug must be continued for more than 2 or 3 days. Signs of dantrolene toxicity include muscle weakness, lethargy, vomiting, diarrhea, and crystalluria.

Pregnant and Breast-Feeding Patients

The US Food and Drug Administration (FDA) has assigned dantrolene to pregnancy category C, meaning that there have been teratogenic effects reported in animal studies. The safety of dantrolene use during pregnancy has not been established. Minor skeletal abnormalities not attributable to teratogenicity were observed in offspring of rats and mice given 60 mg/kg of dantrolene by mouth [55, 56]. No adverse effects were observed in sheep given therapeutic doses or in their offspring [57]. There are several case reports where dantrolene was used during pregnancy without apparent harm to the fetus [58, 59]. In two small case series involving pregnant women, dantrolene crossed the placenta but caused no apparent harm to the mothers or the neonates. Neonatal dantrolene serum concentrations were 40–70% those of the mothers [49, 50]. Dantrolene also has been detected in breast milk of a mother who was being treated for malignant hyperthermia after an emergency cesarean section. Her peak breast milk concentration was 1.2 $\mu\text{g/mL}$ (3.8 $\mu\text{mol/L}$) 36 h after birth. The half-life of dantrolene passing through breast milk was 9 h [60].

Contraindications

Other than prior allergic reactions, there are no contraindications for short-term intravenous use of dantrolene. Long-term oral therapy (>45 days) is contraindicated in patients with active hepatic disease because of the possibility of exacerbating liver damage. Dantrolene also is contraindicated in patients who depend on spasticity to maintain posture or locomotion.

Precautions

Intravenous dantrolene has a pH of 9.5. It can cause irritation to peripheral veins and significant tissue loss if extravasation occurs. During the infusion, care must be taken to ensure that the

catheter tip is placed within a large nonmovable vein and that the solution is infused slowly enough to prevent backflow into surrounding tissue.

Each 20-mg vial of dantrolene contains 3 g of mannitol. This source of mannitol should be considered when a patient receives additional mannitol to preserve renal function. Patients should be monitored carefully for evidence of dehydration and pulmonary edema while receiving dantrolene. Patients with impaired cardiac or pulmonary function may be particularly susceptible to developing acute respiratory distress syndrome (ARDS) during intravenous therapy.

On the day of intravenous administration, patients may experience difficulty swallowing, so they should be monitored carefully during meals for choking. Because dantrolene's muscle relaxant effects may last 48 h after intravenous administration, patients who recover quickly should avoid ethanol and sedative drugs, and be cautioned not to drive or operate heavy machinery.

Dantrolene should be avoided in patients taking calcium channel antagonists. Anesthetized swine given therapeutic intravenous doses of both verapamil and dantrolene developed rapid-onset third degree atrioventricular block, hyperkalemia, and cardiovascular collapse [61]. Similar results were seen in dogs [62]. There is a single human case report of hyperkalemia and myocardial depression after concomitant administration of dantrolene and verapamil. A 60-year-old man treated with verapamil for coronary artery disease was given dantrolene 30 min before surgery. At 2.5 h after the infusion finished (45 min after surgery was completed), his cardiac index decreased from 2.1 to 1.9 L/min/m² and his serum potassium increased to 7.1 mmol/L, despite an otherwise uneventful hemicolectomy. He was treated with insulin, and his condition improved over 4 h. Six months later, the same patient received dantrolene before another surgical procedure. He had been switched to nifedipine 2 weeks before surgery and this time did not develop hyperkalemia or myocardial depression [63]. The exact mechanism

responsible for this adverse effect is unknown. It is possible that myocardial depression results from a combination of slow calcium channel blockade and suppressed calcium release within the myocardium. Hyperkalemia may result from an enhanced release of potassium from muscle secondary to a direct effect of dantrolene on muscle or from decreased potassium uptake by the liver, skeletal muscle, and kidneys as a result of decreased cardiac output. Even though the interaction has only been seen with verapamil, the cautionary warning has been extended to all calcium channel antagonists.

Dantrolene may potentiate vecuronium-induced muscle block. A 60-year-old woman given dantrolene and vecuronium before a breast biopsy had a longer recovery period, based on 75% recovery of evoked twitch tension, compared to eight control subjects [64]. Dantrolene may prevent presynaptic neurotransmitter release at the neuromuscular junction through a calcium-mediated process.

Dantrolene can also potentially increase methotrexate and carbamazepine serum concentrations. A 16-year-old girl had elevated methotrexate plasma concentrations after receiving her first dose of methotrexate (12 g/m²) for treatment of osteosarcoma. The patient had received intravenous nalbuphine for 4 days and oral dantrolene for 1 day before methotrexate was started. Her plasma methotrexate concentration rose at 24 h post dose (418 μ mol/L) and she subsequently developed clinical and biological manifestations of methotrexate toxicity. Dantrolene was stopped and the patient eventually was treated successfully with low dose methotrexate. It is thought that dantrolene or 5-hydroxydantrolene reduced serum binding and impaired methotrexate renal elimination [65]. In addition, a 37-year-old woman taking carbamazepine developed elevated serum carbamazepine concentrations with symptoms of intoxication while taking dantrolene and oxybutynin. It is unclear whether oxybutynin, dantrolene, or the combination of the two triggered the apparent reduction in carbamazepine metabolism [66].

Adverse Effects

The adverse effects of dantrolene depend on the dose, route, and duration of therapy. For short-course (3–5 days) intravenous or oral therapy, typical during treatment or prophylaxis for malignant hyperthermia, patients often develop generalized muscle weakness, drowsiness, dizziness, light-headedness, diarrhea, nausea, malaise, and fatigue (24–30% incidence of combined findings) [42, 67, 68]. These effects subside within 2–4 days of continued therapy and are alleviated by reducing the daily dose [69, 70]. Nine percent of patients receiving intravenous dantrolene also may experience phlebitis near the infusion site [67]. Deep vein thrombosis has also been reported [71]. The more serious side effects associated with short-course intravenous therapy are anaphylaxis, respiratory failure, ARDS, and hyperkalemia. There has been one case of anaphylaxis and “rare reports” of dantrolene-associated pulmonary edema, according to the manufacturer. Large diluent and mannitol doses as well as serious underlying cardiovascular disease may have contributed to the development of pulmonary edema. The true incidence of drug-induced anaphylaxis and pulmonary edema is unknown.

Long-term oral therapy has been associated with drowsiness (30%), dizziness (14%), nausea (9%), vomiting (9%), fatigue, and malaise [42]. In addition, patients may experience either constipation (4%) or persistent diarrhea (2.5%). Other, less frequent side effects include constipation, gastrointestinal bleeding, anorexia, swallowing difficulty, gastric irritation, abdominal cramps, speech disturbances, seizure, headache, light-headedness, visual disturbances, diplopia, alteration of taste, insomnia, tachycardia, erratic blood pressure, mental depression, confusion, increased nervousness, crystalluria, hematuria, difficult erection, difficulty urinating, feeling of suffocation, abnormal hair growth, acne-like rash, pruritus, urticaria, sweating, chills, fever, and excessive tearing [72]. Dose-dependent respiratory failure may also occur even in patients without underlying respiratory disease [73]. Urinary retention [74] and pharyngeal spasticity [75] have

also been reported. The two most serious side effects associated with chronic dantrolene therapy are hepatotoxicity and eosinophilic pulmonary effusion; neither of these two effects has been reported with short-course therapy.

Dantrolene-associated hepatotoxicity tends to occur after 1–6 months of long-term oral therapy, usually in patients taking more than 200–300 mg/day. There is a single case of hepatotoxicity after intravenous administration, but this was in a patient who was recovering from orthotopic liver transplantation [76]. Fatalities have clustered in patients older than 35 years of age, women, those with a primary diagnosis of multiple sclerosis, and patients taking dantrolene longer than 6–10 months [77, 78]. These observations are based on two overlapping case series composed almost entirely of voluntary reports to the US Food and Drug Administration. It is impossible to characterize true risk of dantrolene-associated hepatotoxicity without knowing the size and characteristics of the chronic dantrolene user population and without comparing the dantrolene population with a similarly matched control population.

The best estimate of the incidence of dantrolene-associated hepatotoxicity is derived from a review of safety data from premarketing clinical trials involving 1044 patients taking dantrolene for at least 60 days. In this group, 1.8% of patients taking dantrolene on a long-term basis developed abnormal liver function tests, 0.6% showed clinical manifestations of hepatotoxicity, and 0.3% died as a direct result of hepatotoxicity [77]. Large doses were used regularly in these trials, so it is possible that the true incidence of hepatotoxicity is lower with current dosing. In a subsequent series of 243 patients taking ≤ 400 mg daily, one patient developed hepatotoxicity. This patient had chronic hepatitis B and was taking 400 mg dantrolene daily [68].

Clinical manifestations are not sensitive indicators of hepatotoxicity during long-term dantrolene therapy. In four patients undergoing liver biopsy after suspected dantrolene-induced hepatotoxicity, two patients had no clinical symptoms but had marked hepatic necrosis on biopsy specimen [79]. Both asymptomatic

patients were identified through routine screening. When dantrolene produces liver injury, serum transaminase enzymes are mildly elevated (100–600 IU). Fatality is more common with total serum bilirubin in the range of 15–19 mg/dL (257–325 $\mu\text{mol/L}$) [78]. Liver biopsy specimens usually show changes consistent with chronic active hepatitis, submassive necrosis, massive necrosis, or bridging necrosis [77–80]. The underlying mechanism for dantrolene-associated hepatotoxicity is poorly understood. Studies in rats have shown that dantrolene or one of its metabolites inactivates mixed-function oxidase and binds strongly to hepatic proteins. This activity is enhanced when reduced glutathione stores are depleted [81, 82].

The treatment for dantrolene-induced hepatotoxicity is discontinuation of the drug. In most instances, serum transaminases and bilirubin return to normal within 1–12 months [77].

Another rare, but serious, side effect of long-term dantrolene therapy is eosinophilic pleural effusion. Fifteen cases have been published to date [83–91]. In two instances, the patients also had drug-induced pericarditis. The onset ranges from 2 months to 15 years. Patients usually present with cough, dyspnea, shortness of breath, low-grade fever (38–38.5 °C), and moderate peripheral and pleural eosinophilia. The chest radiograph showed unilateral or bilateral pleural effusion. In all instances, the patients recovered after discontinuation of the drug. None of the patients underwent dantrolene rechallenge. There is no discernible pattern in dose, gender, or age. The exact pathophysiology of this adverse effect is unknown.

Indications

Injectable dantrolene sodium is approved by the US Food & Drug Administration for treatment of malignant hyperthermia crisis. The injectable product has been used off-label for treating MDMA intoxication, neuroleptic malignant syndrome, tetanus, and heat stroke. Oral dantrolene sodium has been approved by the FDA for treatment of chronic spasticity and for treatment of

Table 2 Strength of evidence supporting clinical use of dantrolene

Use	FDA approval	Highest level of evidence supporting use	Efficacy	Reference(s)
Malignant hyperthermia crisis	Yes	II3	Effective	[6]
MDMA intoxication	No	III	Effective	[14]
Neuroleptic malignant syndrome	No	II2	Inconclusive	[94–96]
Tetanus	No	II3	Effective	[7]
Heat stroke	No	I	Inconclusive or potentially ineffective	[97, 98]
Spasticity (all causes)	Yes	I	Inconclusive or potentially effective	[99]
Spasticity, multiple sclerosis	Yes	I	Inconclusive or of limited effectiveness	[100, 101]
Spasticity, cerebral palsy	Yes	I	Inconclusive	[102]
Spasticity, stroke	Yes	I	Inconclusive or potentially effective	[103, 104]

malignant hyperthermia. Table 2 shows the strength of evidence supporting FDA approved and other uses. The beneficial impact of intravenous dantrolene is clearer for malignant hyperthermia than for treatment of chronic spasticity. For malignant hyperthermia, the mortality rate decreased from 64% in the 1960s [92] to 9.5% [93] in 2012 with use of dantrolene. Dantrolene's use in the treatment of chronic spasticity is based on double-blind placebo controlled clinical trials conducted in the 1970s and 1980s. These trials usually had nonvalidated outcome measures, unclear diagnostic criteria, poorly described randomization methods, and potential threats to blinding. In addition, these trials were of short duration (<6 weeks). The reduction in spasticity was often associated with significant muscle weakness, limiting dantrolene's use to a small group of tolerant patients.

Administration

The preparation of intravenous dantrolene varies by brand. Dantrium[®] and Revonto[®] brands of dantrolene for injection are prepared by adding 60 mL of sterile water for injection to each 20-mg vial of lyophilized product. The vials are shaken

until the contents are clear. The reconstituted product should then be administered by continuous intravenous push into a large nonmovable vein. Reconstituted drug can also be administered by transferring the appropriate dose to a sterile plastic bag (not glass) that is protected from light. Each Ryanodex[®] vial contains 250 mg of lyophilized dantrolene that is reconstituted with 5 mL of sterile water. Each Ryanodex[®] vial should be shaken until there is a uniform suspension without particulate matter. The reconstituted product is either administered into an IV line where 0.9% sodium chloride or 5% dextrose are already running freely, or, into a patent flushable indwelling catheter. Ryanodex[®] should not be transferred to another container or diluted before use. Only sterile water should be used for reconstitution of intravenous dantrolene products. Intravenous dantrolene should be stored at 15–25 °C and must be used within 6 h of reconstitution.

The dosage of dantrolene for treating suspected malignant hyperthermia is 2.5 mg/kg given by rapid intravenous administration until end-tidal carbon dioxide concentration, temperature, muscle stiffness, and heart rate decline. This dose may be repeated as frequently as needed until the patient responds. Most patients will respond to

cumulative doses of <10 mg/kg; however, larger doses are sometimes needed for patients with persistent contractures or rigidity. After an appropriate loading dose has been infused, the patient should be started on a maintenance regimen to prevent recrudescence of malignant hyperthermia. The maintenance regimen consists of multiple infusions of 1 mg/kg every 4–6 h or a continuous infusion of 0.25 mg/kg/h with a total duration of at least 24 h [105, 106]. Longer infusions and higher administration rates are sometimes needed [107]. Since recrudescence occurs in 20% of cases, continuous monitoring is needed for 48–72 h after the initial incident [105, 108]. A pharmacokinetically based regimen has also been proposed that increases maintenance infusion rates with the size of the loading dose required [48]. Dantrolene’s ability to prevent complications associated with malignant hyperthermia diminishes with time. Ideally, it should be administered within 10 min of event detection. In one study, dantrolene was ineffective in preventing malignant hyperthermia complications if given beyond 50 min of the onset of clinical effects [109]. Dantrolene should not be used prophylactically [28]. The use of dantrolene in the treatment of this condition is discussed in greater detail in ► Chap. 29, “Malignant Hyperthermia.”

Oral dantrolene has been administered through a nasogastric tube when intravenous dantrolene was not available. One patient was treated with 4 mg/kg of dantrolene as a suspension in 50 mL sterile water given twice within 30 min [110]. This technique should be used only as a last resort since dantrolene’s absorption may be erratic, and the onset of action will be delayed.

A dantrolene oral suspension can be prepared by mixing the contents of an appropriate number of dantrolene capsules into a simple syrup containing citric acid (150 mg/100 mL final product) with or without preservative (0.15% methyl hydroxybenzoate). This suspension is stable at 5 °C, 25 °C, and 40 °C (104 °F, 41 °F, and 77 °F) for 150 days. It should be dispensed in high-density polyethylene bottles and should be shaken before use. Fawcett and associates recommended assuming a shelf life of 30 days for the suspension [111].

Table 3 Typical dose titration regimens for treating spasticity

Adults	Children
25 mg once daily for 7 days	0.5 mg/kg twice daily
25 mg three times daily for 7 days	0.5 mg/kg three to four times daily
50 mg three times daily for 7 days	Incrementally increase each dose by 0.5 mg/kg
100 mg three times daily for 7 days	Do not exceed 3 mg/kg four times daily or 400 mg/day

The oral doses of dantrolene used for treating spasticity vary by age and by patient response. Adults are given 25 mg/day initially [112]. The dose should be increased in 7-day increments until limb functionality is improved. Dosage should not exceed 400 mg/day. Pediatric patients are given 0.5 mg/kg twice daily. Children may be gradually titrated to larger daily doses by increasing the dosing frequency first and then increasing each dose. The total maximum pediatric dose should be no greater than 12 mg/kg/day or 400 mg/day [72, 113]. For all patients, the lowest effective dose should always be used [72] (Table 3).

Dosages used to treat neuroleptic malignant syndrome (Level of evidence II2) are 1–2.5 mg/kg intravenously, followed by 1 mg/kg every 6 h for 48 h, followed by tapering oral doses of 25–600 mg/day depending on response [114]. Most patients respond within 12 h [39]. See ► Chap. 31, “Neuroleptic Malignant Syndrome” for more information.

The Malignant Hyperthermia Association of the United States recommends that all anesthetizing suites be stocked with enough dantrolene to treat a 70 kg patient with 10 mg/kg of drug [115].

Azumolene

Azumolene is an equipotent analogue of dantrolene. It is 30 times more water soluble than traditional injectable forms of dantrolene sodium (e.g., Dantrium[®], Revonto[®]). It was created by substituting the *para*-nitrophenyl group of dantrolene with a *para*-bromophenyl group. Based on in vivo animal studies and a small

number of in vitro human muscle tests, azumolene appears to have the same pharmacodynamic properties as dantrolene [38, 116]. Efforts to advance azumolene as a potential replacement for dantrolene ceased due to concerns about its hepatotoxic effects [30].

Deferoxamine is a chelator used for acutely ill iron-poisoned patients. It can also be used as an aluminum chelator and in the treatment of transfusional iron overload states. Its use in critically-ill patients is, however, almost always confined to patients with acute iron overdose. The treatment of acute iron toxicity is discussed in detail in ► [Chap. 67, “Iron.”](#) This chapter focuses on the clinical pharmacology of deferoxamine for the treatment of acute iron poisoning.

History

In 1964, ferrioxamine D, which is an iron chelate of deferoxamine, was isolated from *Streptomyces pilosus* [1]. Several animal studies verified the efficacy of deferoxamine as a chelator in iron poisoning [2]. In 1966, a clinical series of 172 iron-poisoned children treated with deferoxamine was published [3]. Five years later, the same author published a series of 472 iron-poisoned patients, providing the largest clinical series available on the treatment of iron poisoning with this agent [4], (level of evidence grade II-2).

Properties

Chemical

Deferoxamine (Fig. 1) has a molecular weight of 561 g/mol. It typically is supplied as desferoxamine mesylate (*N*-[5-[3-[(5-amino-pentyl) hydroxycarbonyl] propionamido] pentyl]-3-[(5-(*N*-hydroxyacetamido) pentyl) carbonyl] propionhydroxamic monomethane sulfonate (salt). Its molecular formula is $C_{25}H_{48}N_6O_8$.

Physical

Deferoxamine is usually supplied as a lyophilized powder with a white to off-white color. It is highly water soluble. It has no odor, or its odor is subtle. The melting point of deferoxamine is 148–149 °C.

Pharmacodynamics

Deferoxamine binds ferric (Fe^{3+}) iron in a 1:1 M ratio with an affinity constant approximating 10 [31, 1, 4]. Deferoxamine has low affinity for other common ions (with the exception of aluminum), including ferrous (Fe^{2+}) iron [1]. The structure of the deferoxamine-iron chelate ferrioxamine is shown in Fig. 1.

There is some uncertainty regarding the compartment from which deferoxamine removes iron. Given its hydrophilic nature and molecular weight of 561 g/mol, its cellular permeability is likely

limited [1, 5–7]. In addition to the various molecules for which it has a physiologic function, such as hemoglobin, myoglobin, and cytochrome oxidase, iron is stored in the form of ferritin and transported in the blood primarily bound to transferrin. After absorption from the gastrointestinal tract as ferrous iron, it is oxidized to the ferric form and bound to transferrin. Under normal conditions, almost all circulating iron is bound to transferrin, and it is this bound form which is generally reflected in routine serum iron determinations. Transferrin has a molecular weight of approximately 90,000 d, and each molecule is capable of binding two ferric ions. Typically, only about one third of transferrin's iron-binding sites are occupied, and it serves as a natural chelator when free serum iron is present. Normally, there is some iron release, particularly from the reticuloendothelial system, where hemoglobin and red blood cells are broken down. In this situation, the iron is released in the form of ferritin in small amounts.

In iron toxicity, the iron-binding capacity of transferrin is exceeded. Deferoxamine does not remove significant amounts of transferrin-bound iron [8]. Non-transferrin-bound iron usually has a serum half-life of 60–120 min. It is therefore assumed that deferoxamine's major mode of action is its ability to chelate non-transferrin-bound serum iron [9], level of evidence grade II-1. It is intuitively apparent that deferoxamine has the capacity to chelate the fraction of serum iron that, being unbound, may be most likely to be responsible for intercellular transport and toxicity. A dose of 100 mg of deferoxamine has the capacity to bind 8.5 mg of iron. The fraction of

Fig. 1 Chemical structures of deferoxamine (a) and the ferrioxamine B chelate (b)

deferoxamine that enters cells may chelate unbound or weakly-bound intracellular iron.

There are no prospective controlled studies verifying deferoxamine's efficacy in the treatment of acute iron poisoning. Considerable data exist, however, in patients treated for iron overload states, indicating that iron reduces serum ferritin and, when given on a long-term basis, reduces intracellular iron deposition [10].

Pharmacokinetics

The pharmacokinetic profile of deferoxamine in acute iron poisoning is poorly characterized. There is a small body of data from patients with transfusional iron overload states and from studies with volunteers, however, which allows for some conclusions concerning relevant pharmacokinetic parameters. Deferoxamine is poorly absorbed orally and should not be given by this route. In the case of acute iron ingestion, it is possible for ferrioxamine, the deferoxamine-iron chelate, to form in the gastrointestinal tract after oral administration of deferoxamine. However, this situation may enhance iron toxicity because of the greater absorption of iron in the chelated form and the intrinsic toxicity of ferrioxamine.

Pharmacokinetics of Deferoxamine

Oral absorption: poor

Volume of distribution: 0.6–1.33 L/kg

Excretion in breast milk: unknown

Mode of clearance: metabolism followed by renal metabolite elimination

Elimination half-life: 3–6 h

Cleared by extracorporeal techniques: yes

Although clinically significant deferoxamine concentrations are achievable by all parenteral routes, only the intravenous route generally is used in the case of acute iron poisoning. The pharmacokinetic correlation of deferoxamine in relation to the hemodynamic perturbations associated with acute iron poisoning has not been characterized for the intramuscular or subcutaneous routes, and administration by these routes

should be avoided if possible. After intravenous administration, deferoxamine follows a two-component elimination profile, consisting of a fast initial distribution half-life of 5–10 min followed by an elimination half-life of approximately 3 h [11]. Steady-state was achieved in 6–12 h in volunteers receiving an intravenous deferoxamine infusion [11]. In a canine model, a steady-state serum concentration of 10.7 µg/mL was achieved with an infusion dose of 10 mg/kg/h [12].

Deferoxamine not renally cleared has two potential fates. One is to complex with iron to form ferrioxamine; the other is to be metabolized hepatically [11, 13–15]. The degree of metabolism depends on the chelatable iron status of the patient. The primary metabolite of deferoxamine is called *metabolite B*. When formed, deferoxamine metabolites are excreted renally. In healthy volunteers, renal clearance accounts for 30% of total deferoxamine clearance [16].

Deferoxamine has been reported to have a volume of distribution of 0.6–1.33 L/kg [1, 13, 17]. It distributes into the intracellular compartment and can chelate intracellular iron [1, 5–8]. Deferoxamine is removable by hemodialysis and other extracorporeal drug removal techniques [18, 19].

Ferrioxamine has a volume of distribution of only 0.2 L/kg and has an initial half-life of 2.3 h, followed by a terminal half-time of 5.8 h in volunteers [16]. Similar to deferoxamine, ferrioxamine can be removed by extracorporeal techniques [20–22].

Special Populations

Pregnant and Breast-Feeding Patients

There have been several cases of treatment of iron-poisoned pregnant women with deferoxamine without an evident harmful effect to the fetus [23–25]. In women with thalassemia being treated with deferoxamine, there seemed to be no adverse effects on the fetus [25–27, level of evidence grade III]. Deferoxamine is a highly charged molecule and is unlikely to cross the placenta, a prediction verified in an ovine model

[28]. The logical conclusion, therefore, is that based on the current state of our knowledge iron poisoning in pregnancy should be treated in a fashion similar to that in nonpregnant patients (Grade III recommendation). It is unknown whether deferoxamine is excreted in breast milk; it is prudent, therefore, to suspend breast-feeding during administration of this agent.

Contraindications

As with all agents, a known allergic reaction to deferoxamine should be considered to be a contraindication. Because deferoxamine and ferrioxamine are excreted renally, patients with renal failure should receive this agent only in association with hemodialysis. If the renal failure is prerenal, aggressive fluid resuscitation can be followed by standard deferoxamine therapy. Because hypotension is a major acute complication of deferoxamine administration, it is prudent to closely monitor the hemodynamic status of patients with renal insufficiency during deferoxamine infusions. Patients with compromised renal function may not be able to tolerate infusion rates that are appropriate to those who can excrete deferoxamine and ferrioxamine normally.

Precautions

The precautions associated with deferoxamine therapy for acute iron poisoning relate to the potential adverse effects described in detail below.

Adverse Effects

The major adverse effects associated with the use of deferoxamine in the treatment of iron poisoning are hypotension, acute renal failure, a pulmonary syndrome, *Yersinia* sepsis, and allergy. Many additional effects have been reported with long-term use of deferoxamine as an iron chelator for the treatment of iron overload states such as thalassemia major, hemosiderosis, or

hemochromatosis. These effects have little relevance to the use of deferoxamine in the treatment of acute iron intoxication and are not discussed further in this chapter. For additional information regarding these toxicities, the reader is referred to an excellent review on this topic by Bentur et al. [29] (level of evidence grade III).

Hypotension and Shock

There have been several reports of hypotension and shock associated with intravenous deferoxamine therapy [4, 30, 31]. Most sources recommend that hypotension can be avoided if doses of deferoxamine do not exceed 15 mg/kg/h. It is likely, however, that the intravascular volume depletion associated with iron poisoning may contribute to the hypotension, and substantially higher doses may be tolerated (Grade III recommendation). The dose rate is best determined based on the clinical response in an appropriately volume-resuscitated patient. It also is possible that histamine release may contribute to the hypotension [31, 32]. One article reported, however, that the use of H₂ antagonists did not prevent deferoxamine-induced hypotension [31, level of evidence grade II-2].

Acute Renal Failure

Acute renal failure has been reported after deferoxamine administration [33–35]. It seems that this renal injury is related to decreased renal perfusion associated with intravascular volume depletion as is typically seen in acute iron poisonings. A study of intravenous deferoxamine administration to dogs showed that it causes decreased renal perfusion independent of changes in systemic blood pressure, an effect preventable in this model by intravascular volume expansion [33]. Based on this, intravascular volume resuscitation should be started before deferoxamine administration; this should be accomplished by a bolus rather than delaying therapy by a slow infusion (Grade III recommendation).

Acute Respiratory Distress Syndrome

Beginning around 1990, several reports [36–38] described a pulmonary syndrome in patients who received high doses of deferoxamine for prolonged periods for the treatment of iron overload states [36, 37] or iron poisoning [38]. This syndrome occurred within 32 h to 9 days of continuous high-dose deferoxamine therapy and was associated with noncardiogenic pulmonary edema, tachypnea, hypoxia, fever, eosinophilia, cough, and diffuse pulmonary infiltrates. Some of the patients had urticaria before the development of the syndrome. Pulmonary function tests in one of the patients being treated for thalassemia major showed a restrictive pattern; however, the interpretation is confused by the high incidence of pulmonary abnormalities in patients with thalassemia [37]. In the early 1990s, several reports appeared of fatalities in patients with acute respiratory distress syndrome after deferoxamine treatment for iron poisoning [38, level of evidence grade III]. Subsequently, several other reports also described acute respiratory distress syndrome in patients who had received prolonged or high-dose deferoxamine therapy [34, 39, 40]. Because these patients generally were treated for prolonged periods, it is unlikely that 24 h of deferoxamine therapy, even at high doses, represents an increased risk for the development of acute respiratory distress syndrome. If treatment is continued for more than 48 h, it is prudent, based on the above, to monitor patients carefully for the development of this syndrome.

Yersinia Sepsis

There have been several reports [41, 43] of patients being treated with deferoxamine for acute iron poisoning or iron overload secondary to thalassemia major who developed infections due to *Yersinia enterocolitica*. Although patients with thalassemia have increased susceptibility to *Y. enterocolitica*, it is likely that the deferoxamine enhances the possibility of sepsis by this organism

[42, 44–47]. Normally, *Yersinia* proliferation is limited by its iron dependency. Deferoxamine can substitute for iron, however [42]. It also is possible that the excess iron from an iron overdose may stimulate *Yersinia* virulence, even in the absence of deferoxamine therapy.

Allergy

Several reports of apparent allergic and anaphylactoid reactions to deferoxamine therapy have been published. The early studies by Whitten and associates [31] reported that deferoxamine induces release of histamine, which may play a role in these reactions. A patient with an apparent anaphylactic reaction, including laryngospasm [48], subsequently was desensitized and was able to continue receiving deferoxamine therapy for thalassemia.

Interference with Iron Assays

Deferoxamine interferes with iron determinations by several routine assays [49, 50]; this occurs not because of deferoxamine-related interfering color but because its chelating qualities interfere with the iron-binding reagents used in the assays. Atomic absorption and plasma emission spectrophotometric assays are unaffected by the presence of deferoxamine and are recommended for iron quantitation during deferoxamine therapy. A deferoxamine-insensitive modification of the routine automatic clinical analyzer method of iron determination has been published [51].

Administration

As reviewed previously and in ► Chap. 67, “Iron,” deferoxamine should be administered by the intravenous route in all patients with acute systemic iron poisoning. Because of the concern for hypotension in these often volume-depleted patients, it is important to administer fluid resuscitation aggressively to these patients as soon as

possible. It is not necessary to complete fluid resuscitation before starting deferoxamine therapy; both can be accomplished simultaneously (Grade III recommendation).

The rate of deferoxamine infusion, as described earlier, is best individualized on the basis of patient tolerability. Although a maximal rate of intravenous infusion of 15 mg/kg/h is often cited, there is little empirical justification for this recommendation. In a severely iron-poisoned patient who is able to tolerate higher doses, there is no reason to restrict the rate of infusion to this parameter. Most acutely iron-poisoned patients require less than 48 h of deferoxamine treatment [52]. Because of concerns for deferoxamine-induced acute respiratory distress syndrome, as described earlier, treatment with this agent should be restricted to less than 48 h if possible.

In normal intermediary metabolism, six adenosine triphosphates (ATPs) are created by passing two pairs of electrons down the respiratory chain from two reduced nicotinamide adenine dinucleotides to molecular oxygen. In the course of this mitochondrial ATP synthesis, the iron in cytochrome *aa₃*, the terminal oxidative respiratory enzyme, is oxidized from the ferrous (Fe^{2+}) to the ferric (Fe^{3+}) form. Cyanide has a special affinity for the ferric heme, blocking oxygen consumption and oxidative phosphorylation. Blood contains a great quantity of ferrous heme within hemoglobin that can be converted to the ferric form (methemoglobin) by the use of methemoglobin-generating agents. If methemoglobin is formed in excess of total body cytochrome *aa₃*, the cyanide ion binds to methemoglobin, restoring normal cellular respiration (Fig. 1).

The use of nitrite for methemoglobin formation was suggested by Chen and colleagues [1] in 1933, and nitrite is still used to treat cyanide poisoning. A theoretical disadvantage of nitrite therapy, however, is that methemoglobinemia is induced slowly. The originally suggested dose of 4 mg/kg intravenously results in 6% of methemoglobin after only 40 min [2]. A high dose of nitrite, if given too quickly, may lead to vasomotor relaxation and hypotension [3]. Amyl nitrite, which is administered by inhalation, creates little methemoglobin [4], but similar to nitrite, it has a vasodilating effect. Another cyanide antidote, dicobalt ethylenediamine tetraacetic acid (“cobalt EDTA”), can cause severe reactions, such as

urticaria, hypotension, convulsions, and laryngeal edema [5, 6].

The antidote with the least side effects is hydroxocobalamin, which is discussed in the chapter on Cyanide-Binding Antidotes [7]. The latter is expensive, however, and has practical disadvantages. It can be given only in a large volume 5 gr in 250 mL, and the lyophilized powder must be first reconstituted. This process may be too time-consuming in a critically poisoned patient. A compound that quickly creates sufficient methemoglobin with few adverse effects would be preferable. 4-Dimethylaminophenol (4-DMAP) may have advantages regarding these criteria.

History

4-dimethylaminophenol was developed and studied in the laboratories of the Walther Straub Institute for Pharmacology and Toxicology of the Ludwig Maximilian University in Munich, Germany. The German army supported its development because it was thought that hydrogen cyanide might be used as a chemical warfare agent.

In 1969, Kiese and Weger [8] reported that 4-DMAP was the most potent methemoglobin-forming agent among a series of aminophenols tested in humans for the treatment of cyanide poisoning. 4-Dimethylaminophenol was used in human cyanide poisoning successfully by Daunderer et al. in 1972 [9]. Because severe cyanide poisoning has become rare, only single case reports have been published since. A series of 13 cases in which 4-DMAP was given to humans between 1973 and 1979 has been described in a thesis from our department; however, these cases have not been published elsewhere [10]. A further series of nine cases from our department, from 1981 to 1991, was published as an abstract [11]. We are aware of the use of 4-DMAP in Austria and the Netherlands [12]. 4-Dimethylaminophenol is registered as a pharmaceutical by the German authorities (BfArM). Permission for its use was extended in 2003. At the very moment, it is not acquirable as the firm has to

alter the way of synthesis. But stocks are still on most German emergency ambulances (Notarztwagen NAW). The producer of this drug is the company Dr. Franz Koehler Chemie GmbH, Bensheim, Germany.

Properties

The properties of 4-DMAP are summarized as follows:

Chemical name: Dimethyl (para) aminophenol hydrochloride (Fig. 2)

Chemical formula: $C_8H_{11}ON \cdot HCl$

Relative molecular mass: 173.5

Appearance: White crystals

CAS (Chemical Abstracts Service) number: 619-60-3

Raw material: White colorless crystals

Melting point: $145^\circ C \pm 1^\circ C$

Solubility: Soluble in water. The solution is oxidized by contact with air and changes from colorless to black-brown.

Pharmacodynamics

4-Dimethylaminophenol produces methemoglobin by catalytic transfer of electrons from ferroheme to oxygen. This process is terminated by binding of oxidized 4-DMAP to compounds that possess free SH groups (see Fig. 1).

In human volunteers, 3.25 mg/kg of 4-DMAP given intravenously oxidized about 30% of the total hemoglobin to methemoglobin (Fig. 3) [13]. The spontaneous reduction of methemoglobin back to ferroheme was 8% per hour at 30% to 20% of methemoglobin levels [14]. In vivo, 1 molecule of 4-DMAP is capable of converting 15 molecules of hemoglobin to methemoglobin [13]. Methemoglobin formation by 4-DMAP occurs rapidly. In experiments on seven volunteers [2], an intravenous bolus of 3.25 mg/kg of 4-DMAP resulted in 15% methemoglobin after 1 min and 28.5% after 10 min. The peak of 30% was attained after 20 min.

Fig. 1 Mechanism of action of cyanide, 4-DMAP, and methemoglobin. *Cyta₃* cytochrome *aa₃*

Fig. 2 Chemical structure of 4-dimethylaminophenol

4-Dimethylaminophenol can be administered intramuscularly or orally. The intramuscular injection of 3.5 mg/kg of 4-DMAP in human volunteers ($n = 6$) resulted in a maximal measured methemoglobin concentration of 30% after 45 min. The administration of 12 mg/kg of

4-DMAP orally ($n = 5$) created 27% methemoglobin within 30 min, but the actual oral bioavailability is uncertain [13].

4-Dimethylaminophenol (3.25 mg/kg) given intravenously to dogs 1 min after poisoning with potassium cyanide (4 mg/kg) that is twice the lethal dose in dogs [15] resulted in the survival of all dogs [16]. The peak concentration of methemoglobin was $32\% \pm 1.9\%$ [16].

4-Dimethylaminophenol has other effects on physiologic functions. Although the venous lactate

Fig. 3 Course of methemoglobin concentrations in cyanide-poisoned patients and human volunteers after intravenous administration of 4-DMAP [10]. *bw* body weight

concentration did not change, the pyruvate concentration increased by 30% after 4-DMAP administration. This effect also was found in canine blood in vitro, most probably caused by the lactate-induced methemoglobin reduction [14, 17].

In dogs [17], the mean arterial pressure after 4-DMAP (3.25 mg/kg intravenously) increased by 15% within 5 min, and the effect was maintained for 1 h. The respiratory minute volume increased by 30%. Both effects may be advantageous in cyanide poisoning. The arterial PO_2 increased within 1 min from 95 to 190 mmHg, after which it normalized by 10 min. This increase has been attributed to the release of oxygen from oxyhemoglobin during the formation of methemoglobin. It is possible that in a critically ill, cyanide-poisoned patient, this may improve tissue oxygenation [17]. When cerebral blood flow was measured in canine brain [18], 4-DMAP evoked a dose-dependent increase in cerebral blood flow. The positive cerebral blood flow response did not occur until at least 10% methemoglobin was formed. As long as the methemoglobin concentration was less than 40%, the canine brain could compensate for the diminished oxygen transport capacity by elevating oxygen use as indicated by a decrease of pO_2 in the sinus sagittalis. At higher methemoglobin concentrations, oxygen use no longer could be improved [18]. A 4-DMAP dose producing more than 40% methemoglobin is not

advisable. As long as methemoglobin is less than 40%, most physiologic reactions to 4-DMAP seem to be favorable for treating cyanide poisoning.

Pharmacokinetics

In humans and dogs, 4-DMAP (3.25 mg/kg intravenously) is cleared rapidly from the blood with a half-life of less than 1 min [19]. This rapid clearance is due to various first-pass effects [13]. Using [14]C-labeled 4-DMAP in canine experiments, approximately one third of 4-DMAP equivalents were found in red blood cells, and two thirds were found in plasma and the extracellular space (apparent volume of distribution 0.17 L/kg) [20]. To understand the particular pharmacokinetics of 4-DMAP, one must differentiate between the metabolism in erythrocytes and elsewhere, mainly in the liver.

Metabolism of 4-DMAP in Erythrocytes

The distribution of 4-DMAP between plasma and erythrocytes is not known because of the ultra-short lifetime of 4-DMAP within red blood cells. 4-Dimethylaminophenol is cooxidized quickly with oxyhemoglobin to form methemoglobin

and a phenoxyl radical. The phenoxyl radical oxidizes deoxyhemoglobin, sustaining the catalytic cycle of methemoglobin formation [21]. Alternatively, the phenoxyl radical disproportionates to form 4-DMAP and a quinone imine that is bound covalently to hemoglobin SH groups [22]. In the presence of high glutathione concentrations, such as occurs in erythrocytes, the quinoneimine undergoes sequential addition/oxidation reactions with formation of mono-glutathione, bis-glutathione, and tris-glutathione adducts of 4-DMAP [23]. The trisubstituted conjugate is not oxidized further but is actively excreted from the erythrocyte into plasma [24]. This conjugate has a half-life of about 1 h in plasma and is processed further by the kidneys and excreted mainly as a tris-cysteinyl derivative of DMAP [25], as has also been observed in dogs [20]. It has been calculated that probably all 4-DMAP thioethers excreted (15% of the dose) originate from the metabolism of 4-DMAP within the red blood cells. About the same amount of 4-DMAP is bound covalently to the hemoglobin SH groups.

Metabolism of 4-DMAP in the Liver

About 50% of the 4-DMAP administered intravenously to humans is transformed in the liver to the glucuronide and sulfate conjugate. In urine, 41% 4-DMAP glucuronide and 12% 4-DMAP sulfate were detected [13, 25]. This conjugation seems to occur rapidly, as shown in the isolated, hemoglobin-free perfused rat liver, in which covalent binding to liver proteins or formation of glutathione conjugates were of no importance [26]. The first-pass effect in the liver may be the reason for the much higher oral dose compared with the parenteral dose of 4-DMAP required to obtain an equivalent degree of methemoglobin [13].

Toxicity

The toxicity of 4-DMAP has been studied in mouse, rat, and dog. The median lethal doses are listed in Table 1. In all studies, the cause of death

Table 1 Median lethal doses in mice, rats, and dogs

Route/species	Median lethal dose (mg/kg)
Intravenous/mouse	50–70 [27, 28]
Oral/mouse	946 [28]
Intravenous/rat	57 [29]
Oral/rat	689–780 [28]
Intravenous/dog	26 [30]

was severe methemoglobinemia. Single intravenous injection of 4-DMAP (100 mg/kg) to rats was followed by a large amount of necrosis and inflammation of the convoluted tubules without affecting the glomeruli and papillae. No changes were found in the liver, heart, and spleen [27]. In isolated, hemoglobin-free perfused rat kidneys, 4-DMAP underwent a sharp increase of covalent binding to kidney proteins at concentrations greater than 15 μ M. Microautoradiography [14] showed that the high binding was particularly prominent in the proximal convoluted tubules [31].

Special Populations

No data for neonates or children are available. In our series of 23 patients in whom 4-DMAP was used, the eldest person was 66 years old (case 13) (Tables 2 and 3). This patient received 9.3 mg/kg of 4-DMAP. He developed mild hemolysis, with an increase in lactate dehydrogenase to 378 U/L, a decrease in hemoglobin from 13.8 to 10 g/dL within 5 days, and an increase in bilirubin to 3 mg/dL. Because this was nearly three times the recommended dose and hemolysis occurs in younger patients at similar doses, we could not detect a difference between elderly and younger people in reacting to this dose.

Contraindications

Patients with glucose-6-phosphate dehydrogenase deficiency who are unable to reduce methemoglobin by the pentose phosphate shunt are at risk of developing long-lasting methemoglobinemia after 4-DMAP and may have severe hemolysis.

To our knowledge, the drug was never used in such a case. On theoretical grounds, glucose-6-phosphate dehydrogenase deficiency is a contraindication for the use of 4-DMAP. Given the desperate situation of a potentially fatally poisoned patient, we recommend that this be considered only a relative contraindication in cyanide poisoning. If a glucose-6-phosphate dehydrogenase-deficient patient were treated with 4-DMAP, because the enzyme deficiency was unrecognized or it was thought that the treatment was mandated because of life-threatening cyanide poisoning, the induced hemolysis could be treated by transfusion or blood exchange. In whites in Europe, glucose-6-phosphate dehydrogenase deficiency is a rare disease.

Clinical Experiences with Use of 4-DMAP in Cyanide Poisoning

Limited data are available for the use of 4-DMAP in cyanide poisoning because of the rarity of such poisonings and because few such poisoned persons are found alive. Some single case reports are published [9, 12, 32–34] (Grade III evidence). All but one of these case reports describe patients who survived, probably reflecting a publication bias.

Since 1972, our department has accumulated 23 cases of cyanide poisoning treatment by 4-DMAP either before or at the time of admission and one case in which 4-DMAP was used by mistake (see Tables 2 and 3): 13 cases were published in a thesis by Werner in 1979 [10], 1 case (number 10) was published by Daunderer and coworkers [9], and 9 additional cases were published in an abstract [11].

In the original Werner series, the indications for administering 4-DMAP were less strict than they are today. Of the 13 patients, only 4 (see Table 2), found in coma, seemed to meet the absolute indications we use today. Three of these four patients survived. In two further cases (cases 8 and 9 in Table 2), the indications for 4-DMAP were questionable. One patient was somnolent and still arousable. The other patient was in a coma, but 5 h had elapsed since the poisoning. In 1981 (when the first author joined the

department), the indications for 4-DMAP administration were clarified. Cases of mild cyanide poisoning were treated with sodium thiosulfate. Since 1981, nine patients received 4-DMAP: five survived, three died, and one was dead for an unknown period before he was found. From the eight remaining cases, three had to be resuscitated at the scene. In all three cases, it was possible to restore circulation after the administration of 4-DMAP. Two of the patients died of irreversible brain damage or edema after brain death had ensued, and one fatally rearrested after 3 h. All patients who were found in deep coma without cardiac arrest or without severe circulatory failure survived. Of the group of 12 patients (excluding the one who was found dead, the one who got the antidote after 5 h, and all the cases in which the indication was doubtful), 8 survived and 4 died. 4-Dimethylaminophenol has not been studied in a controlled trial comparing its efficacy with other cyanide antidotes.

Dose

Considering the optimal 4-DMAP dose for a severely poisoned patient, the clinician has to keep in mind that exact dosing is difficult for the patient in extremis, the exact weight or height of the patient is unknown, and calculations under stress are difficult. We recommend that a standard dose, based on animal studies and clinical experience, be one ampule (equivalent to 3.25 mg/kg of 4-DMAP in a 76-kg person). As can be seen from Table 2, 125 mg was administered in 2 cases (cases 3 and 20), and 250 mg was administered in 13 cases. One patient (case 21) who could not be saved had mild hemolysis. One patient received 375 mg of 4-DMAP (case 19) in two divided doses and died on day 5 with severe hemolysis. All five patients (cases 7, 13, 14, 15, and 16) who were given 500 mg showed mild-to-severe hemolysis. One patient (case 18) received 1000 mg and developed severe hemolysis with a peak methemoglobin content of 73%; the patient survived. Another patient treated with 1000 mg of

Table 2 Data in 23 patients in whom 4-DMAP was administered^a

Case no./year	Cause/route of poisoning	4-DMAP dose/interval before administration	Indication	Adverse effects	Outcome
1/1975	Accident/transdermal	250 mg/12 min	None; not in coma	None	Recovery

^aSodium thiosulfate was administered after 4-DMAP in all patients.

Hb hemoglobin, MetHb methemoglobin

4-DMAP was poisoned with parathion. This patient also survived with severe hemolysis and renal failure (not shown in Table 2 or 3).

Methemoglobin Formation

A dose of 250 mg of 4-DMAP (see Table 3, cases 4, 5, 6, and 12) seems to create methemoglobin concentrations between 33% and 49.5%, which disappeared with a half-life of around 140 min (see Fig. 3). The half-life is not influenced by the dose. In our patients, it was a little bit longer than in normal controls (117 min). As seen in case 7, 500 mg of 4-DMAP can lead to long-lasting methemoglobin formation. It is likely that most of the methemoglobin found in this case after 72 h stemmed from extracellular methemoglobin due to hemolysis.

From this limited experience, we conclude that in a healthy adult, 250 mg is theoretically sufficient, yet safe. Repeated 4-DMAP administrations do not seem to be necessary if sodium thiosulfate is administered subsequently.

Precautions

Before 4-DMAP is used in a patient, it should be certain to the degree practically possible that the patient is poisoned by cyanide. We recommend that 4-DMAP should be used only if the patient is in a coma (Grade III recommendation). We do not recommend its use in smoke inhalation patients because of the theoretical concern that carboxyhemoglobin and methemoglobin jointly may impair oxygen transport and delivery.

Table 3 Whole-blood cyanide and methemoglobin levels in 23 patients in whom 4-DMAP was administered

Patient	Cyanide level/time after intoxication	Dose 4-DMAP	Methemoglobin/time after 4-DMAP
1	Negative/1 h	250 mg	23 %/13 min
2	Not measured	250 mg; 4.38 mg/kg	Not measured
3	Negative/150 min	125 mg; 2.7 mg/kg	Not measured
4	Positive in breath/90 min	250 mg; 4.5 mg/kg	49.5 %/27 min
5	Positive in breath/5.25 h	250 mg; 2.7 mg/kg	33 %/9 min
6	0.18 mg/L/9 h	250 mg; 4.3 mg/kg	35.6 %/3 min
7	Not measured	500 mg; 8.3 mg/kg	35 %/72 h
8	1.5 mg/L/15 min	250 mg	Not measured
9	3 mg/L/15 min	250 mg; 4 mg/kg	14.7 %/1 h
10	Not measured	250 mg	Not measured
11	Not measured	250 mg; 3.57 mg/kg	22 %/13 min
12	2 ppm in breath/2 h	250 mg; 5 mg/kg	41.2 %/25 min
13	Not measured	500 mg; 9.3 mg/kg	Not measured
14	2.4 mg/L/2 h	250 mg/10 min; 250 mg/3 h	15.8 %/1 h; 37.7 %/155 min after second administration
15	6.0 mg/L/2.25 h	500 mg	Not measured
16	25 mg/L/1 h	500 mg	33.4 %/130 min
17	1.46 mg/L/130 min	250 mg	Not measured
18	Positive in breath	1000 mg	73 %/1 h; 46 %/3.5 h
19	2.65 mg/L	250 mg; 125 mg	Not measured
20	34 mg/L/1.5 h	125 mg	Not measured
21	10.9 mg/L/2 h	250 mg	19 %/15 min
22	14 mg/L	250 mg	14.8 %/45 min
23	Not measured	500 mg	Not measured

Adverse Effects

Two major adverse effects are related to the desired action of 4-DMAP: excessive methemoglobinemia and hemolysis. Our cases suggest that significant hemolysis does not occur at doses of 5 mg/kg body weight. The suggested dose of 3.25 mg/kg did not produce excessive methemoglobinemia. Only in one fatal case of cyanide poisoning was excessive methemoglobinemia observed using the recommended dose of 4-DMAP [12]. In vitro, the methemoglobin production rate at atmospheric oxygen pressure was only 60% of that at 40 mmHg, similar to that in venous blood [35]; this may be important in hypoxic patients when cardiopulmonary insufficiency is present. In our opinion, this fact should not lead to reducing the

dose in such circumstances as long as the patient is ventilated with a fraction of inspired oxygen of 1.

Some minor adverse effects are of little relevance in severely poisoned patients. Phlebitis was observed 6–7 days after 4-DMAP was infused in the antecubital vein. After an intramuscular injection of 4-DMAP, slight pressure was felt after 5–10 min at the site of injection, slowly growing in intensity and finally resulting in severe pain in one patient. In another patient, shivering, sweating, and fever occurred approximately 10 h after the injection. In volunteers, after the intravenous injection of 4-DMAP (3.25 mg/kg), the total bilirubin concentration increased by 140%, conjugated bilirubin increased by 180%, and iron increased by 200%. Within 24 h of an intramuscular injection of this dose, the total bilirubin

increased by 270% and then declined rapidly, whereas the conjugated bilirubin concentration increased by 120% and iron increased by 50% [13].

Treatment of Adverse Effects

Excess methemoglobinemia may be corrected by 2 mg/kg of toluidine blue or by 1 mg/kg of methylene blue intravenously [36]. We suggest that this should be done only if within 1 h after the administration of 4-DMAP the methemoglobin level exceeds 50% (Grade III recommendation). Otherwise, cyanide can be released, and thiosulfate infusion is mandatory. Exchange transfusion is needed if the methemoglobin level remains high as this means that methemoglobin comes from erythrocytes that have lysed and therefore cannot reduce MetHb.

Administration

4-Dimethylaminophenol should be administered in a dose of 3.25 mg/kg intravenously in a comatose, cyanide-poisoned person (Grade III recommendation). In adults, it seems reasonable to administer one ampule of 4-DMAP, which contains 250 mg, if the exact weight is not known. It is possible to administer 4-DMAP in the same dose intramuscularly in mass poisoning.

Final Evaluation

Animal experiments and limited clinical data suggest that 4-DMAP is an effective antidote against cyanide poisoning. Although in most cases it was used in combination with sodium thiosulfate and therefore it is difficult to distinguish the efficacy of the two drugs. Single cases have received DMAP only successfully. There was, in most cases, an improvement shortly after its administration and before the use of sodium thiosulfate, suggesting that 4-DMAP is effective. In cases of severe cyanide poisoning, 4-DMAP is probably lifesaving, if administered in time. 4-DMAP produces more

MetHb more rapidly than nitrites, although it has to be acknowledged that since both treatments have an equal chance of successful outcome, the speed of forming MetHb might not be of utmost importance. It should not be used in the case of smoke inhalation since the induced methemoglobinemia may be additive to CO poisoning. However, there is no evidence that it has ever been tested in such circumstances. The possibility to administer 4-DMAP intramuscularly might make it an appropriate antidote for severe cases in the industrial environment and for use in treatment of mass casualties, e.g., in terror attacks [37].

Dimercaprol is the generic term for 2,3-dimercaptopropanol. Because British investigators developed dimercaprol during World War II as an antidote to the war gas lewisite, it also came to be known as the *British anti-lewisite* or *BAL*.

History

The development of dimercaprol as an antidote to the organoarsenical agent lewisite (dichloro [2-chlorovinyl] arsine) extended earlier observations that the action of arsenoxide drugs involved biochemical interaction with the thiol groups of enzymes and that this process could be mitigated by a large excess of sulfhydryl reagents. After screening many monothiol and dithiol chemicals, Peters and coworkers [1] found that the dithiol compound 2,3-dimercaptopropanol was most effective at preventing lewisite-induced inhibition of pyruvate oxidase and protecting experimental animals from lewisite's vesicant and lethal effects. A penetrating oily liquid dimercaprol initially was conceived of as a topical treatment for lewisite burns to the eyes and skin. Subsequent studies found that topical and intramuscular injections of dimercaprol alleviated severe dermatologic and systemic complications associated with organoarsenical antibiotics used in the treatment of syphilis [2]. Within 3 years, the use of dimercaprol extended to treatment of poisoning by inorganic heavy metals, particularly inorganic arsenic

Fig. 1 Chemical structure of dimercaprol (2,3-dimercaptopropanol)

and mercuric salts [3]. It still is used for this purpose today.

Chemical and Physical Properties

Dimercaprol (Fig. 1) ($\text{C}_3\text{H}_8\text{OS}_2$; molecular weight 124.2) is an oily, colorless liquid with a skunk-like mercaptan odor. Although soluble in water to 6% (weight/volume), the vicinal thiol groups are readily oxidized in aqueous solutions. To achieve greater stability, the pharmaceutical product is prepared as a 10% solution (100 mg/mL) in peanut oil that also contains 20% (200 mg/mL) benzyl benzoate. Dimercaprol forms 1:1 or 2:1 complexes with several metals *in vitro*; however, the nature of metal complexes formed by dimercaprol or its metabolites *in vivo* has not been determined.

Pharmacodynamics

Dimercaprol increases the urinary excretion of certain toxic metals (particularly arsenic, lead, and mercury). In animal studies, it has been shown to redistribute mercury and arsenic to the brain, however [4, 5]. Dimercaprol increases elimination of copper, an essential trace mineral. In human studies, dimercaprol injection results in a transient increase in blood pressure and heart rate, but it otherwise has no clinically significant pharmacodynamic impact on cardiovascular, hepatic, or renal function.

Pharmacokinetics

In humans exposed to arsenicals, intramuscular dimercaprol is associated with an increase in urinary arsenic excretion that peaks in 2–4 h [6] and then quickly declines. Pharmacodynamic effects, such as increased blood pressure and pulse, peak

at approximately 30 min and resolve within 2 h [7]. Limited observations such as these imply that dimercaprol is absorbed, distributed, and excreted rapidly. After intramuscular injection of radio-labeled dimercaprol to rats, 80% of the radioactivity entered the bloodstream within 1 h [8]. The radiolabel was distributed rapidly and widely to most soft tissues, with the highest levels measured in the kidneys and the liver. Some intracellular distribution has been inferred from the ability of dimercaprol to traverse cell membranes *in vitro* [9], but the drug's volume of distribution has not been determined. After injection in animals, an altered form of dimercaprol is excreted in the urine, with minor amounts in the bile or feces, within 6–12 h [8, 10]. It was observed consistently in rats and rabbits that unchanged dimercaprol was not excreted in the urine. In rabbits, dimercaprol seemed to be metabolized partly to an unspecified thiol compound [11]; in rats, no free thiols were excreted [12].

Contraindications and Precautions

Because it is dissolved in peanut oil, dimercaprol should not be administered to patients who are allergic to peanuts. Dimercaprol has been associated with hemolysis in two patients with glucose-6-phosphate dehydrogenase deficiency [13]; susceptible patients should be monitored for hemolysis during treatment.

Because the metabolites of dimercaprol and the metals it mobilizes are excreted predominantly in the urine, caution should be exercised in administering dimercaprol to patients with severe renal insufficiency. Such caution may include initiating treatment at low dose (i.e., 3 mg/kg every 6 h) and closely monitoring patients for adverse effects and evidence of metal excretion. A few reports suggest that dimercaprol or its metabolites may be dialyzable and that dimercaprol may increase the dialysis clearance of mercury in patients with renal failure [14–16]. Although increased mortality was found when massive doses of dimercaprol were given to animals with acute hepatic damage from carbon tetrachloride [17], no relevant

clinical experience implicates hepatic insufficiency as a contraindication.

Dimercaprol (0.3 mg/kg) did not redistribute radiolabeled mercury to the fetus when administered to pregnant mice concurrently exposed to mercuric chloride [4]. Dimercaprol was teratogenic and embryotoxic, however, at a dose of 125 mg/kg/day in a mouse model, and it seems less effective than succimer or unithiol in averting the adverse reproductive effects of arsenic or mercury [18, 19]. Dimercaprol is rated pregnancy category C by the US Food and Drug Administration.

Adverse Effects

The adverse effects of dimercaprol are dose dependent. Reactions are relatively mild and infrequent at doses of 3 mg/kg intramuscularly or less but occur in two thirds of patients receiving 5 mg/kg intramuscularly. Transient elevation in blood pressure, with an increase in diastolic pressure of 10–40 mmHg, is common at doses of 4 or 5 mg/kg intramuscularly. The blood pressure usually normalizes within 2 h [7]. Compared to adults, children are prone to tachycardia rather than blood pressure elevation after dimercaprol injections [20]. In 60 healthy adults and 61 adults with complications of organoarsenical antisyphilitic therapy, dimercaprol doses of 4–5 mg intramuscularly were associated with the following adverse effects, in decreasing order of frequency: nausea, vomiting, and headache; a burning sensation of the lips, mouth, throat, and eyes, sometimes with accompanying lacrimation, rhinorrhea, or salivation; generalized muscular aches; burning and tingling of the extremities, with sweating of the forehead and hands; pain in the teeth; and a sense of constriction in the chest, with a feeling of anxiety and general agitation. These symptoms appeared within 10–30 min of the injection and subsided within 30–50 min. Fever was observed after the second or third dimercaprol injection in two thirds of children receiving doses greater than 3 mg/kg [20], but this seems to be uncommon in adults. Convulsions and transient coma occurred in three

children who accidentally received dimercaprol injections of 25 mg/kg [20].

One anecdotal report suggested that 25 mg of ephedrine administered (to an adult) 0.5 h before dimercaprol injection may diminish the severity of subsequent adverse effects [21]. This has not been a consistent observation, however, and ephedrine conceivably might aggravate the pressor response of dimercaprol. Intramuscular injections of dimercaprol frequently are perceived as painful and may be complicated by sterile or pyogenic abscesses. Prior local injection of procaine has been suggested as a means to diminish the pain associated with intramuscular dimercaprol injection [22].

Administration

Dimercaprol (BAL in oil) is supplied as 3 mL ampules containing dimercaprol (100 mg/mL) and benzyl benzoate (200 mg/mL) in peanut oil. For the treatment of systemic poisoning by relevant heavy metals, it can be administered only as a deep intramuscular injection. The initial dose ranges from 2.5 to 4 mg/kg intramuscularly every 4–6 h depending on the nature and severity of the poisoning being treated. It is common to progressively taper the amount and frequency of dimercaprol administered during the initial days of therapy. Dimercaprol injections have been used as an experimental topical treatment for vesicant burns to the skin and eye induced by lewisite [23, 24]. A 5% solution prepared by diluting the 10% ampules in vegetable oil should be applied *immediately* to the exposed surface of the eye, conjunctivae, and skin. Systemic effects should be treated parenterally.

Ethylene glycol and methanol toxicity has the potential to cause morbidity and mortality [1, 2]. Along with supportive care and hemodialysis, ethanol has been utilized as a treatment option for many years, first investigated and used in the 1940s and 1950s [3–5].

Although in the past few years the use of ethanol has largely been supplanted by the alcohol dehydrogenase inhibitor, fomepizole [6], it is not always available either because of cost or lack of easy access. Given the need to inhibit formation of the toxic metabolites of ethylene glycol and methanol, initial use of ethanol may be necessary either as a temporizing measure until fomepizole is available or to complete treatment.

Ethanol (C_2H_5OH) is a colorless, hygroscopic, volatile two-carbon alcohol (Fig. 1) with a molecular weight of 46.07 g/mol. It can be synthesized from carbohydrates by the enzyme zymase, found in yeast cells. Ethanol also can be formed through the hydration of ethylene or through the hydration of acetylene to form acetaldehyde, which is further reduced to form ethanol [7].

Ethanol therapy generally mandates an intensive care unit admission regardless of the patient's clinical status. Therefore, it is important that the critical care medicine physician be familiar with the safe and effective use of ethanol in this clinical setting.

Ethylene glycol and methanol poisoning are discussed extensively in their respective chapters.

Fig. 1 Metabolic pathways for ethanol (a), methanol (b), and ethylene glycol (c)

The clinical pharmacology of fomepizole is addressed in ► [Chap. 150, "Fomepizole."](#)

Pharmacodynamics

The most prominent clinical effect of ethanol is initial central nervous system excitation and inebriation, followed by depression. The mechanism of ethanol's effect on the central nervous system is a matter of some debate. Being an amphipathic solvent, the lipophilic portion of ethanol increases the fluidity of cellular membranes. It is not known, however, if this alteration in membrane fluidity is related to the observed effects at clinically relevant concentrations. Ethanol can also cause ataxia, loss of coordination, and mood change. It also modulates the activities of multiple ion channels in the central nervous system.

Pharmacokinetics

Absorption

Ethanol is absorbed directly from the stomach, but primarily from the duodenum and jejunum [8]. In volunteer studies, peak absorption of ethanol was shown to occur at 104 min after a 700-mg/kg ethanol dose in men and 84 min after administration of the same dose in women [9, 10]. Factors such as gender and the presence of food may alter the absorption kinetics of ethanol. Women achieve higher serum concentrations of ethanol than men after oral administration of equivalent doses. This has been somewhat controversially attributed to increased levels of gastric alcohol dehydrogenase in men [11, 12]. Food also decreases gastric emptying which slows ethanol absorption. The area under the curve for ethanol is lower when food is present rather than on an

empty stomach. This is the same whether the food contains fat or carbohydrates [13, 14].

Distribution

Ethanol has a volume of distribution of approximately 0.6–0.7 L/kg. It distributes with total body water and does not bind to plasma proteins or other tissues. Women have a slightly lower V_d than men likely because the average woman has less water and more fat than the average man [15].

Metabolism

The primary enzymes responsible for the metabolism of ethanol are hepatic alcohol dehydrogenase and aldehyde dehydrogenase (Fig. 1a) and, to a much lesser extent, the cytochrome P450-2E1-dependent ethanol-oxidizing system [16]. Some orally ingested ethanol does not enter the systemic circulation because of first-pass metabolism via gastric ADH. The extent of this first-pass metabolism still remains a point of debate. Some studies have shown significant first-pass metabolism while others did not show as large of a change [17–19]. If ethanol is rapidly passed into the duodenum without food present, gastric first-pass metabolism is eliminated, and higher blood alcohol concentrations are observed [16].

Elimination

The average physiologic range of ethanol elimination is 10–25 mg/dL (2.17–5.43 mmol/L) although there is considerable variability. In those with liver disease or who are malnourished, elimination can be as slow as 8–9 mg/dL (1.74–1.95 mmol/L), while in moderate drinkers 15 mg/dL (3.26 mmol/L) is a good average value. For patients who are binge drinkers or alcoholics, elimination can be as high as 25–35 mg/dL (5.43–7.6 mmol/L) [20].

Women tend to eliminate ethanol more rapidly than men; however, this is unlikely significant

enough to merit gender-specific rates [20, 21]. Ethanol undergoes Michaelis-Menton elimination kinetics at low ethanol levels while at levels greater than 10–20 mg/dL (2.17–4.34 mmol/L) elimination follows a zero-order process [20].

Precautions and Adverse Effects

Ethanol can cause a dose-related decreased level of consciousness, ranging from mild inebriation to coma. Rarely this can result in loss of airway protection and respiratory depression requiring intubation, airway management, and assisted ventilation. Although there are many anecdotal case reports describing hypoglycemia after exposure to ethanol especially in children [22–24], retrospective medical record reviews and case series have questioned the actual incidence of this effect [25–28]. Frequent blood glucose measurement is beneficial in recognizing hypoglycemia, which can be treated with supplemental dextrose as necessary.

In a retrospective review of ethanol therapy in cases of pediatric methanol toxicity, no clinically relevant episodes of hypoglycemia were reported. Some children were reported to be drowsy, but none required any type of airway intervention. Hypotension was rare, and there were no children with ethanol-associated hypothermia or hepatotoxicity [29]. Adverse events were more common in two other studies, mostly involving adults, with central nervous system depression and coma, some requiring intubation, and manifesting hypotension, tachycardia, and, in some cases, agitation [30, 31]. These studies also reported difficulty keeping the serum ethanol level within the desired range, a well-documented problem in cases where ethanol is used therapeutically.

During intravenous administration of ethanol, close observation and reevaluation of the IV site is important to prevent local vein irritation, phlebitis, and extravasation. Gastritis and nausea after exposure to oral ethanol are well described. There is also an increased risk for vomiting after oral administration of therapeutic doses of ethanol in children and other ethanol-naïve patients, given the high concentrations and frequent doses

administered. Although allergic reactions, described as anaphylactoid, after ethanol administration are rare, dermatitis and asthma-associated wheezing have been reported [32].

Ethanol should be used very carefully in pregnancy. 1–2 h after maternal ethanol ingestion, fetal alcohol concentrations reach levels nearly equivalent to maternal levels. Ethanol elimination by the fetus is impaired because of reduced metabolic capacity and reabsorption via amniotic fluid [33]. Both ethanol and fomepizole are Pregnancy Category C (there are no well-controlled studies that have been done in pregnant women; it should be used only if the possible benefit outweighs the possible risk to the unborn baby); however, we would recommend the use of fomepizole as it does not have the same clinical effects expected of ethanol.

Treatment

The toxicity of ethylene glycol and methanol are due primarily to the formation of toxic metabolites. In the presence of sufficient concentrations of ethanol, the metabolism of ethylene glycol and methanol to these toxic metabolites is inhibited as a result of competitive inhibition of alcohol dehydrogenase [1]. Compared with methanol, ethanol has approximately 20 times the affinity for alcohol dehydrogenase. Ethylene glycol has an even weaker affinity for alcohol dehydrogenase than methanol, and its metabolism, like that of methanol, can be effectively blocked by ethanol administration. In clinical practice, serum ethanol concentrations of 100–150 mg/dL (21.7–32.5 mmol/L) are targeted for therapeutic ADH-blockade, although this is an empiric range dating back to early investigations of ethanol as an antidote [34, 35] (Grade III evidence). A serum ethanol concentration of 100 mg/dL (21.7 mmol/L) significantly prolongs the elimination half-life of ethylene glycol and methanol from approximately 4 h and 8 h to approximately 18 h and 52 h, respectively [36, 37].

The indication for ethanol therapy is the same for the initiation of fomepizole in the treatment of methanol or ethylene glycol toxicity. These

indications are discussed in detail in the chapters on Methanol, Ethylene Glycol, and Fomepizole.

The most frequently used biological matrices in which ethanol concentrations are measured are serum, blood, and breath. During therapeutic administration of ethanol for ethylene glycol and methanol poisoning, frequent monitoring (every 1–2 h) of serum ethanol concentration (the most common matrix utilized in hospitals) is mandatory to ensure that concentrations are maintained at greater than 100 mg/dL (>21.7 mmol/L) and to avoid development of toxicity.

Administration

Both intravenous and oral ethanol can be used in the treatment of ethylene glycol and methanol toxicity. Some advantages to intravenous ethanol are complete and rapid absorption, bypass of first-pass metabolism, and avoiding the gastrointestinal upset associated with oral ethanol. A maximum concentration of IV ethanol of 10% is generally recommended and well tolerated. The loading dose of ethanol is usually administered over 30–60 min. Although less-concentrated solutions such as 5% may be helpful in decreasing the risk of venous irritation, fluid overload is also possible due to the large volume required. When oral ethanol is used, it is generally recommended that solutions should be diluted to 20% and administered over 30 min to decrease the risk of gastritis and vomiting. This is particularly important in children and other ethanol-naïve patients.

There are different approaches to the dosing of ethanol. Based on pharmacokinetic parameters, one recommendation has been to use a loading dose of 600 mg/kg (13 mmol/kg or 6 mL/kg of ethyl alcohol [EtOH] 10%) [35, 37, 38]. These authors also recommend maintenance doses of 109 mg/kg/h (2.4 mmol/kg/h or 1.1 mL/kg/h of EtOH 10%). (Grade III recommendation) As ethanol is also dialyzable, doses during hemodialysis of 237 mg/kg/h (5.1 mmol/kg/h or 2.4 mL/kg/h of EtOH 10%) are recommended.

However, because of the variations from ongoing metabolism, many clinicians use larger doses. One approach utilizes an ethanol

loading dose of 700–1000 mg/kg (15.2 mmol/kg to 22 mmol/kg or 7 mL/kg of EtOH 10%). This is followed by a maintenance dose of 60–130 mg/kg/h (2.7–3.3 mmol/kg/h or 1.25–1.5 mL/kg/h of EtOH 10%) for a nonchronic drinker and 100–154 mg/kg/h (2.2–3.4 mmol/kg/h) for more ethanol-tolerant patients. If the patient is also undergoing hemodialysis, the maintenance dose is generally increased to 250–275 mg/kg/h (5.4–6 mmol/kg/h or 2.5–2.75 mL/kg/h of EtOH 10%) [38, 39] (Grade III recommendation).

In the absence of pharmaceutical-grade ethanol, other alcohol sources, such as vodka, can be used for oral ethanol therapy. Vodka, or other 80-proof alcoholic beverage, provides a 40% ethanol solution. An approximate oral ethanol loading dose is 2.5 mL/kg, with maintenance doses from 0.2 to 0.4 mL/kg/h. It is useful to dilute this with juice or another mixer to make it more palatable to ethanol-naïve patients. Nonsedating antiemetics such as ondansetron are recommended for ethanol-associated nausea.

The influence of insulin on the heart was studied as early as the 1920s [1]. Efficacy of insulin and glucose as a possible antidote for beta-blocker and calcium channel blocker-induced cardiogenic shock was demonstrated by Kerns and Kline in the 1990s. These early animal studies confirmed not only improved hemodynamics but also improved survival over glucagon and epinephrine in xenobiotic-induced myocardial depression. Subsequently, a report of high-dose insulin therapy used as a treatment for drug-induced cardiovascular shock in humans was reported [2–4]. Since then, insulin and dextrose have been used to treat not only calcium channel blocker and beta-blocker overdoses but also polypharmacy overdoses with myocardial depression.

Currently, the only formulation of insulin or glucose demonstrated as an effective antidote for drug-induced cardiovascular shock is intravenous (IV) regular human insulin and dextrose. Therefore, this chapter will not discuss other formulations of insulin or glucose. All references to insulin in this chapter refer to IV regular human insulin, and all references to glucose refer to IV dextrose solutions.

History

In 1921, Dr. Frederick Banting, at the University of Toronto, created a pancreatic extract by isolating “isletin” from pancreatic islet cells. Isletin

K. Engebretsen (✉)
Department of Emergency Medicine, Regions Hospital,
Minneapolis, MN, USA
e-mail: kmengebretsen@gmail.com

later became known as insulin. Banting first tested his extract in dogs, and then in 1922, insulin was successfully used to treat a 14-year-old patient with diabetes who lay dying in Toronto General Hospital. Insulin was then administered to other children with diabetes and had a phenomenal response in waking children from diabetic coma. Banting was awarded the Nobel Prize in Physiology or Medicine, and the patent for insulin was sold to University of Toronto for one dollar [5].

Insulin's beneficial effects beyond simple control of hyperglycemia soon became apparent, and the use of the drug expanded into the management of critical care issues such as sepsis, heart failure, and cardiac drug toxicity.

Positive inotropic effects of insulin were described as early as 1927 by Visscher et al. [1]. Research in the 1970s went on to examine the effects of glucose, insulin, and potassium (GIK) on myocardial free fatty acid substrate metabolism. These studies demonstrated the ability of high-dose insulin to increase left ventricular function in patients with myocardial infarction/ischemia and to increase cardiac index in patients with cardiac shock following cardiac bypass surgery [6, 7].

Insulin's mechanisms of action in drug-induced cardiovascular shock are complex and not completely understood. However, the three primary suggested mechanisms of action of high-dose insulin in xenobiotic-induced cardiovascular shock that result in increased inotropy are increased myocardial glucose utilization, vasodilation, and calcium signaling. Each of these mechanisms is discussed more in depth below.

Augmentation of myocardial contractility through exogenous administration of supplemental glucose alone has not been shown to be of benefit in experimental models [8]. Under normal conditions the heart uses free fatty acids as its primary source of energy [9]. In times of stress, myocytes and other cells shift to utilization of carbohydrates for their primary cardiac energy source [9]. One example of this is calcium channel antagonist toxicity. Calcium channel antagonists block L-type calcium channels in

myocardial cells, smooth muscle cells, and beta cells resulting in bradycardia, conduction delays, peripheral vasodilation, hypoinsulinemia, hyperglycemia, metabolic acidosis, and shock. Hypoinsulinemia may result in decreased uptake of glucose by myocytes causing a loss of inotropy and decreased peripheral resistance. Exogenous insulin administration increases glucose uptake by myocytes leading to improved inotropy, decreased peripheral vascular resistance, increased lactate uptake by cells, and reversal of acidosis [10–12].

The second mechanism by which high-dose insulin therapy is thought to result in increased inotropy is through peripheral vasodilation. High-dose insulin does not increase mean arterial pressure (MAP) through vasopressor activity. Insulin is actually a vasodilator of the systemic, coronary, and pulmonary vasculature [13]. Vasodilatory effects are due to enhancement of endothelial nitric oxide synthase [13]. In cases of beta antagonist or calcium channel antagonist overdose, significant myocardial depression is observed, resulting in decreased cardiac output and a decrease in MAP. While vasopressors increase MAP, afterload is also increased resulting in increased cardiac workload and oxygen demand. These effects acting on an already struggling heart could result in cardiac arrest. High-dose insulin causes peripheral vasodilation, allowing for increased mechanical efficiency of the heart, increased cardiac output, and an increase in both macrovascular and microvascular perfusion without increasing workload or oxygen demand [1, 3, 10].

The third proposed mechanism for the inotropic effects of high-dose insulin is the result of increased calcium signaling. Insulin helps to facilitate transmembrane calcium influx by accelerating the reverse mode of the sodium/calcium exchanger, resulting in increased inotropy [14]. Calcium is the major intracellular signal required for pyruvate dehydrogenase activation. Inhibition of mitochondrial calcium entry at the sarcolemma and mitochondrial membrane decreases pyruvate dehydrogenase activity. Decreased availability of pyruvate for the Krebs

cycle results in lactate accumulation and metabolic acidosis [4, 15–18].

High-dose insulin also regulates/reduces cytosolic calcium concentrations. Insulin enhances activity of sarcoplasmic–endoplasmic reticulum calcium ATPase, which improves contractility by increasing binding of troponin I and protein C in myofibrils, enhancing excitation coupling [19].

High-dose insulin therapy has multiple other effects which are just beginning to be understood, such as suppression of tumor necrosis factor α , interleukin 6, pro-inflammatory cytokines, and free radical production, all of which contribute to hypotension [20]. Insulin facilitates the release of nitric oxide and regulates interleukins 4 and 10 possibly protecting against apoptosis as well as ischemic and reperfusion injury associated with shock [21]. Insulin's role in increased expression of β 1-adrenoreceptors and intramyocardial calcium-handling genes in human myocardial cells is also being explored [22, 23].

Properties of Regular Human Insulin

Amorphous insulin was the first form made available for clinical use. Further purification afforded crystalline insulin that is now commonly called regular human insulin.

Physical: Recombinant human insulin is an off-white powder.

Regular human insulin is crystalline zinc insulin dissolved in a clear solution.

Chemical: Insulin injection USP is a solution made from crystalline zinc insulin.

Regular human insulin is a 51-residue peptide hormone composed of two amino acid chains covalently linked by disulfide bonds. Recombinant insulin is synthesized by recombinant DNA technology with a molecular formula of $C_{257}H_{383}N_{65}O_{77}S_6$ and a molecular weight of 5807.69 Da. This recombinant human insulin is chemically, physically, and biologically identical to pancreatic human insulin [24–26] [24. Level of Evidence: III] [25. Level of Evidence: II-3] [26. Level of Evidence: II-3].

Pharmacodynamics

Insulin pharmacodynamics refers to the metabolic effect of insulin. The pharmacodynamic effects of IV regular human insulin are significantly different than subcutaneous administration [26] [26. Level of Evidence: II-3].

In insulin overdose, the duration of action is extended and the peak effect delayed [27] [27. Level of Evidence: III]. The reasons for these pharmacodynamic effects include accumulation effect of insulin and extended insulin half-life secondary to insulin receptor saturation with exogenous insulin [28] [28. Level of Evidence: III].

The dosing of insulin when it is used as an antidote for drug-induced cardiovascular shock is significantly different than how it is dosed for treatment of diabetes or diabetic ketoacidosis. Insulin when used as an antidote for drug-induced cardiovascular shock is typically given as a 1 u/kg IV bolus, and then an IV infusion of 1–2 u/kg/h is started and may be titrated up to 10 u/kg/h. Given the significantly higher dosing of insulin when used as an antidote for drug-induced cardiovascular shock, it would be expected that insulin's duration of action and half-life may be much longer than that when administered for diabetic diagnoses.

Pharmacokinetics

Pharmacokinetics of IV Regular Human Insulin

- Onset, 10–15 min [29]
- Peak, 15–30 min
- Duration, 30–60 min

Level of Evidence: II-3

Although recombinant human insulin is chemically, physically, and biologically identical to pancreatic human insulin, the pharmacokinetics of exogenously administered regular human insulin

does differ from endogenous insulin released by the pancreas. The main reason is that the pancreas releases insulin into the portal vein where it undergoes a first-pass effect with more than 50% of released insulin being extracted by the liver. As a result, hepatic exposure to insulin is high, and peripheral (muscle, fat) exposure to insulin is low. On the other hand, exogenously administered insulin is distributed throughout the circulation, exposing the peripheral organs to relatively high concentrations due to its lack of first-pass effect and relatively lower concentrations to the liver [29] [29. Level of Evidence: II-3].

IV bioavailability, 100%

Volume of distribution, 0.15 L/kg:

- The volume of distribution is equal to the volume of the extracellular fluid (i.e., approximately 20% of the body weight.)
- Insulin is present in plasma as a free monomer. It diffuses into tissues and crosses the blood–brain barrier [30] [30. Level of Evidence: II-3].

Protein binding, 5%

Pregnancy category: B

- Studies show that endogenous insulin only crosses the placenta in minimal amounts. Recombinant human insulin is identical to endogenous hormone and would not be expected to produce teratogenic effects.

Excretion in breast milk: endogenous insulin is present in human milk. Insulin orally ingested is degraded in the gastrointestinal tract. No adverse reactions have been associated with infant exposure to insulin through the consumption of human milk.

Elimination half-life, 6 min (in healthy subjects and patients with diabetes)

- Insulin is inactivated by several enzymatic biotransformations: hydrolysis by metalloproteinases

and reduction, i.e., cleavage of disulfide bonds [31] [31. Level of Evidence: II-3].

- Renal insulin elimination is low because after filtration it is reabsorbed by the tubule [31] [31. Level of Evidence: II-3].
- The kidneys and liver account for the majority of insulin degradation. With endogenous release of insulin from the pancreas, approximately 60% is metabolized hepatically and 35–45% renally [32, 33] [32. Level of Evidence: II-3] [33. Level of Evidence: II-3].
- Exogenously administered insulin metabolism is slightly different as it is not delivered directly to the portal vein. Renal degradation accounts for approximately 60% and hepatic metabolism about 30–40% [32, 33] [32. Level of Evidence: II-3] [33. Level of Evidence: II-3].
- Renal impairment will reduce the clearance of insulin and prolong its effect. This decreased clearance is seen with both endogenous and exogenous insulin administration. In general, this decreased clearance is not clinically relevant until renal function is significantly diminished [32, 33] [32. Level of Evidence: II-3] [33. Level of Evidence: II-3].

Cleared by extracorporeal techniques:

- Plasma insulin appears to be removed by hemodialysis [34] [34. Level of Evidence: I].

Contraindications

The major specific contraindication to insulin administration is hypoglycemia.

Adverse Effects

The most significant adverse effect of insulin is hypoglycemia. True allergic reactions and cutaneous reactions are rare [Level of Evidence: III].

Hypoglycemia

Signs of hypoglycemia (nausea, vomiting, sweating, hyperventilation, tachycardia, labile blood pressure, hyperventilation) and neuroglycopenia (abnormal behavior, altered level of consciousness, lethargy, coma, cerebral edema, hypertonia, hyperreflexia, extensor plantar response) may occur [27] [Level of Evidence: III].

Electrolyte Disturbances

Hypokalemia, hypomagnesemia, and hypophosphatemia may occur. Cardiac adverse effects associated with hypokalemia and hypomagnesemia may cause prolonged QTc. Fluid overload with resultant hyponatremia may also occur.

Pharmacokinetics of Dextrose

Dextrose is a rapidly metabolized source of calories and fluids in patients with hypoglycemia or increased needs of carbohydrates. By increasing blood glucose concentration, dextrose may decrease body protein and nitrogen losses, promote glycogen deposition, and decrease or prevent ketosis if sufficient doses are given [35] [Level of Evidence: II-3].

Parentally injected doses of dextrose undergo oxidation to carbon dioxide and water. Dextrose solutions >5% may be irritating if given by peripheral infusion. Solutions above 10% should be given only by central venous catheter [35].

IV bioavailability, 100%

Volume of distribution:

- May vary depending on concentration administered

Onset:

- Immediate

Peak:

- Immediate

Duration of action:

- Unknown

Pregnancy risk category: C

- Animal reproduction studies have not been conducted with dextrose. It is also not known whether dextrose can cause fetal harm when administered to a pregnant woman or can affect reproduction capacity. Dextrose should be given to a pregnant woman only if clearly needed.

Excretion in breast milk:

- It is not known whether this drug is excreted in human milk. Because many drugs are excreted in human milk, caution should be exercised when dextrose injection is administered to a nursing mother.

Metabolism:

- Metabolized to carbon dioxide and water

Elimination half-life:

- Unknown

Cleared by extracorporeal techniques:

- Glucose is removed by hemodialysis [34] [34. Level of Evidence: I].

Pharmacodynamics of Dextrose

Dextrose is a rapidly metabolized source of calories and fluids for patients [35, 36] [(35) [Level of Evidence: II-3] 36. Level of Evidence: II-3]. While increasing blood glucose levels, dextrose may have a protein- and nitrogen-sparing effect on the body while also promoting glycogen deposition and decreasing ketosis. Parentally injected

doses of dextrose are oxidized to carbon dioxide and water. A 5% solution is isotonic and can be administered peripherally. More concentrated dextrose infusions provide increased caloric intake with less fluid volume but are irritating if given peripherally. Solutions above 10% should be given only by central venous catheter.

Contraindications to Dextrose

- Hypersensitivity to corn products
- Intracranial or intraspinal hemorrhage

Precautions with Dextrose

- Concentrated dextrose solutions >10% should be administered via central vein only after suitable dilution.

Adverse Effects with Dextrose

- Parenteral dextrose is hypertonic and may cause phlebitis and thrombosis at the site of injection.
- Significant hyperglycemia and possible hyperosmolar syndrome may result from too rapid administration.

GIK Treatment

Insulin as an antidote has been reported in both human and animals to treat drug-induced cardiovascular shock. A recent systematic review concluded that although low quality, the strongest evidence for pharmaceutical intervention supports high-dose insulin for calcium channel blocker-induced cardiovascular shock [37] [37. Level of Evidence: III].

GIK Administration

Regular human insulin is administered IV. It is strongly recommended that a central line be placed for dextrose administration as

concentrations >10% are extremely irritating to the veins [12, 38, 39, 42] [12. Level of Evidence: III] [38. Level of Evidence: II-3] [39. Level of Evidence: III] [42. Level of Evidence: III]. Also, concentration of administered fluids will likely need to be considered to avoid pulmonary edema.

Dextrose

If blood glucose is <200 mg/dl, administer 25 g of dextrose to adults or 0.25 g/kg for children (given as 10–25% dextrose IV push). Blood sugars should be monitored every 10 min while titrating insulin. Once the insulin infusion and blood glucose concentrations are stabilized, monitor glucose concentrations every 30–60 min. No human studies currently exist to verify the frequency at which blood glucose concentrations should be monitored when using high-dose insulin as an antidote. Therefore the author recommends monitoring blood glucose concentrations every 10 min to avoid any significant or sustained hypoglycemia. In the authors' opinion, glucose levels should be maintained between 100 and 200 mg/dl while insulin is being used as an antidote. Although this blood sugar concentration is higher than what is typically desired for a critical care patient in the intensive care unit, short-term hyperglycemia within this range (100–200 mg/dl) likely has more benefits than risks in this situation allowing for flexibility while administering insulin and decreased incidences of hypoglycemia in the patient. Dextrose infusions should be started to maintain a blood glucose > 100 mg/dL (5.6 mmol/L). Additionally, concentrated dextrose infusions >10% administered through a central line may be required to maintain normal glucose concentrations. No equation exists that can accurately calculate the amount of dextrose a patient will need while receiving high-dose insulin therapy. Variability depends on the patient, the medications taken in overdose, and the amount of insulin administered. However, in an insulin dosing study by Cole et al., the author found that the hypoglycemic effects of high-dose insulin therapy actually saturated in his study; the

animals administered 5 u/kg/h of insulin required more dextrose than the animals that received 10 u/kg/h [40] [40. Level of Evidence: I]. Patients receiving 5–10 u/kg/h doses of insulin may require 150 g or more of dextrose per hour. Administration of this amount of dextrose requires administration of a concentrated dextrose solution through a central line to avoid phlebitis as well as pulmonary edema and fluid overload. The pharmacy should be contacted to help prepare a concentrated dextrose solution. Concentrated dextrose solutions of 50% or greater have been used by the author in this type of situation given through a central line.

Insulin

Administer an insulin bolus of 1 u/kg IV push; then start an IV continuous infusion of regular human insulin at 1–2 u/kg/h. The insulin infusion can be titrated up by 2 u/kg/h every 10 min up to a maximum of 10 u/kg/h if desired cardiac output or clinical improvement is not obtained. In general, no human dosing studies were available at the time this chapter was written for high-dose insulin therapy. Dosing is based off of animal studies and case reports [38, 40] [38. Level of Evidence: II-3] [40. Level of Evidence: I].

In Cole et al.'s dosing study, the maximum dose of insulin studied was 10 u/kg/h based off of prior canine studies by Kerns and Kline [2, 3, 10, 40] [2. Level of Evidence: I] [3. Level of Evidence: I] [10. Level of Evidence: I] [40. Level of Evidence: I]. However Cole et al. did not see a plateau in MAP or CO in this study at a dose of 10 u/kg/h. Therefore the maximum response dose is unknown and may require doses higher than 10 u/kg/h. Engebretsen et al. reported a therapeutic misadventure in which a patient received 23 u/kg/h of insulin by mistake. Upon attempts to decrease the insulin infusion, the patient could not be titrated down to 10 u/kg/h and required a dose of 17 u/kg/h for more than 24 h to treat his toxin-induced cardiac shock [41] [41. Level of Evidence: III].

Potassium

Monitor potassium every 60 min while titrating insulin and dextrose solutions to avoid significant hypokalemia. Once insulin infusions have stabilized, monitor potassium concentrations every 6 h. Supplement potassium if concentrations drop below 2.8–3 mEq/L (2.8–3 mmol/L). Typical ICU guidelines may routinely allow for potassium supplementation when potassium concentrations decrease to less than 3.5 mEq/L. However, in high-dose insulin therapy, potassium is shifted intracellularly and does not reflect a true potassium loss from the body. Therefore aggressive replacement of potassium is not recommended in order to prevent hyperkalemia upon discontinuation of high-dose insulin therapy. Caution should be noted in patients who have bradycardia and a prolonged QTc. These patients may be at increased risk of torsades de pointes. Since potassium plays a crucial role in QTc prolongation and torsades de pointes, the author recommends maintaining potassium concentrations in the normal range (3.5–5 mEq/L) in this case to avoid increased risk of torsades de pointes.

Other

Magnesium and phosphorous concentrations also need to be monitored during high-dose insulin therapy. These electrolytes play an important role with potassium in the body. High-dose insulin therapy may significantly affect potassium concentrations and therefore, these electrolytes need to be monitored as well as potassium.

Goals

Perfusion of essential vascular beds and organs needs to be maintained (assessed not by increased BP or mean arterial pressure alone) [42] [42. Level of Evidence: III]. Instead, if possible, assess by mental status, skin warmth and color, peripheral pulses, urine output, and vital signs.

Insulin's action as an inotrope and a vasodilator typically results in minimal effects on systolic blood pressure. Traditional hemodynamic parameters such as maintaining a mean arterial pressure >60 mmHg, a systolic blood pressure >90 mmHg, and an HR >50 may not be obtainable. Noninvasive cardiac output monitoring, if available, will add significant data to assess the efficacy of HDI on contractility and cardiac output of the heart.

Discontinuing Insulin Dextrose Infusions

Currently there are no evidence-based recommendations on the best way to discontinue insulin and dextrose therapy. The insulin infusion may be titrated down or turned off. It is expected that with the administration of high-doses of insulin, the duration of action and half-life may be extended, and hypoglycemia may occur up to 24 h after the insulin infusion has been stopped [43] [41. Level of Evidence: III].

Flumazenil (Romazicon®) (US brand names are given here as examples. These may be the same or different in other countries.) is a specific benzodiazepine receptor antagonist that has generated debate regarding its clinical indications since its initial release in the USA in 1991. A major argument against the use of flumazenil in the management of benzodiazepine intoxication is the relatively high safety index (i.e., toxic-to-therapeutic dose ratio) of benzodiazepines, even in cases of overdose. In addition, the anticonvulsant effects of benzodiazepines may be advantageous in individuals simultaneously poisoned with proconvulsant substances, such as tricyclic antidepressants. Another significant concern regarding the clinical use of flumazenil in the emergent management of poisoning is the possibility of precipitating acute withdrawal in individuals with pharmacodynamic tolerance to benzodiazepine receptor agonists. Withdrawal from benzodiazepines is associated with a spectrum of effects, which can include epileptic seizures [1]. These safety concerns have prevented flumazenil from gaining widespread clinical acceptance as a component of the initial pharmacologic management of coma.

Pharmacodynamics

Flumazenil is an imidazobenzodiazepine similar in structure to midazolam (Fig. 1). It is formulated for intravenous administration primarily because

Fig. 1 Chemical structures of midazolam and flumazenil

it undergoes extensive first-pass metabolism after oral administration [2]. Flumazenil was discovered during the screening of compounds for effects at the central nervous system benzodiazepine site on the γ -aminobutyric acid (GABA) receptor complexes of the GABA_A subtype. The latter functions as a ligand-gated chloride (Cl^-) channel [3]. Ligand interactions at the benzodiazepine receptor are of three types: agonists (such as benzodiazepines), which bind to the receptor and enhance the GABA_A-mediated Cl^- influx; inverse agonists, such as certain β -carboline derivatives (Fig. 2), which decrease GABA_A-mediated Cl^- cell entry [4]; and competitive antagonists, such as flumazenil, which prevent binding of agonists and inverse agonists in a dose-dependent manner, suppressing both agonist and inverse agonist effects on the GABA_A receptor (Fig. 3) [5].

Flumazenil has been shown to bind the benzodiazepine receptor based on displacement of radiolabeled diazepam and other benzodiazepines in vitro [6]. In this regard, it is a competitive antagonist of the benzodiazepine receptor that prevents the binding of an agonist to the receptor. Flumazenil's antagonist properties were confirmed when it reversed the effects of patients intoxicated with benzodiazepines [7, 8]. In addition, flumazenil also reverses the sedative hypnotic effects of non-benzodiazepine drugs (e.g., zolpidem, zopiclone, zaleplon) that bind to the benzodiazepine receptor [9–11].

Fig. 2 Model of benzodiazepine/ γ -aminobutyric acid (GABA) receptor interaction. Benzodiazepine agonists (e.g., diazepam) and antagonists (e.g., flumazenil) are believed to bind to a site on the GABA receptor distinct from the GABA-binding site. A conformational equilibrium exists between states in which the benzodiazepine receptor exists in its agonist-binding conformation (above) and in its antagonist-binding conformation (below). In the latter state, the GABA receptor has a greatly reduced affinity for GABA, and as a result the chloride (Cl^-) channel remains closed (From Rang HP, Dale MM, Ritter JM, Gardner P: *Other transmitters and modulators*. In: *Pharmacology*, 4th ed. Philadelphia, Churchill Livingstone, 2001)

Fig. 3 Idealized model of γ -aminobutyric acid (GABA)-benzodiazepine (BZ)-chloride (Cl^-) channel at axosomatic (postsynaptic) inhibitory synapses. (a) Presynaptic and postsynaptic elements. *ap* action potential, *EC* extracellular, *Gad* glutamic acid decarboxylase, *IC* intracellular, *ipsp* inhibitory postsynaptic potential. (b) GABA-BZ receptor interactions influencing permeability of Cl^- channels. *Neutral*: GABA receptor binds GABA (G) with moderate affinity in the absence of BZ ligand. *BZ agonist*: direct BZ

agonist (b) enhances GABA affinity for its receptor, resulting in maximal Cl^- permeability. *Inverse agonist*: inverse agonists bound to BZ receptor result in poor GABA affinity and markedly reduced Cl^- permeability (From Rech RH: *Drugs to treat anxieties and related disorders*. In Brody TM, Lerner J, Minneman KP [eds]: *Human Pharmacology: Molecular to Clinical*, 3rd ed. St. Louis, Mosby, 1998, p 367)

Acute toxicity studies in rodents revealed oral median lethal dose values of flumazenil of 4300–6000 mg/kg [12]. Evaluation in human volunteers showed no serious toxicity in flumazenil doses of 600 mg orally [13] and 100 mg intravenously [14–16]. Positron emission tomography imaging has shown benzodiazepine receptor occupancy of 50% in human adults after an intravenous flumazenil dose of 1 or 2 mg [17].

Pharmacokinetics

Volume of distribution: 1 L/kg

Protein binding: 50%

Oral bioavailability: 16%

Onset of effects: 1–2 min

Peak effects: 6–10 min

Mechanism of clearance: hepatic metabolism to inactive metabolites

Elimination half-life: 0.8 h

Clinical Use

Initial use of flumazenil was limited to reversal of benzodiazepine effects after conscious sedation and regional or general anesthesia [18–30]. Numerous evaluations in patients undergoing procedural sedation with benzodiazepines have shown effective reversal of sedation with flumazenil. It also has been effective after orthopedic, urologic, and other surgical procedures, including studies that enrolled elderly and other high-risk patients [18–31].

Flumazenil may be used with limited risk in the setting of pure benzodiazepine overdose in a non-benzodiazepine-tolerant individual. In this circumstance, flumazenil may be used to reverse the sedative effects of excessive benzodiazepine doses [5, 7, 8, 15, 32, 33]. Controversy exists regarding flumazenil's reversal of benzodiazepine-induced respiratory depression due to the diversity of findings in the few studies performed [34]. In general, studies of effort-dependent respiratory function, such as vital capacity, have supported improvement with flumazenil [35]. This effect may, however, be due merely to improved conscious control of breathing. Studies of effort-independent respiratory parameters, such as the carbon dioxide respiratory response curve, have not consistently shown improvement after administration of intravenous flumazenil [26, 36]. Overall, flumazenil is not indicated for primary reversal of intravenously administered benzodiazepine-associated respiratory depression [26, 34].

The use of flumazenil in the comatose undifferentiated overdose patient is more controversial. Of particular concern are patients who present after concomitant overdose of benzodiazepines and proconvulsant drugs, such as tricyclic antidepressants. Reports of seizures in temporal association with the empiric use of flumazenil in the management of suspected benzodiazepine overdose emerged early in clinical use [37–43]. Seizures following flumazenil administration are most likely to result from three possible mechanisms: (1) removal of the benzodiazepine-mediated anticonvulsant protection against the proconvulsant effects of other drugs, (2) the

precipitation of acute benzodiazepine withdrawal in the benzodiazepine-tolerant individual, or (3) due to reversal of the anticonvulsant effect of a drug in a patient with a history of seizures [38]. Accordingly, overdose patients considered at risk for flumazenil-associated seizures include patients who are benzodiazepine tolerant, who are treated for seizures or have a seizure disorder, or who have ingested a proconvulsant drug [38].

Given the concern for flumazenil-associated seizures, one retrospective study stratified 35 comatose overdose patients into two groups – one considered “low risk” (i.e., flumazenil use was considered safe and effective) and the other “non-low risk.” The authors defined “low risk” based on the following criteria: no clinical findings consistent with stimulant exposure, no known chronic benzodiazepine use, no known seizure disorder, and no QRS or QT prolongation on ECG. Patients who did not meet these low-risk criteria were categorized as “non-low risk.” In the low-risk group were four patients, and the use of flumazenil resulted in no adverse outcomes; however, 5/31 (16%) of patients in the non-low-risk group had a seizure. Based on the authors' criteria, few comatose patients are likely to meet low-risk criteria for safe flumazenil administration [39].

Clinicians should be aware of the possibility of seizures or acute benzodiazepine withdrawal, manifested by agitation, and peripheral hyperadrenergic signs after flumazenil administration [44–47]. Should seizures occur after flumazenil administration, we recommend initial treatment with standard dosing of benzodiazepines or another GABAergic agent, such as barbiturates. In cases of persistent seizure activity after flumazenil administration that have been treated with standard benzodiazepine or barbiturate dosing, we recommend administration of higher doses of these medications [38].

Administration of flumazenil to overdose patients has been rarely temporally associated with cardiac dysrhythmias [37]. Isolated reported cardiac complications of flumazenil administration have included cardiac arrest [48], ventricular tachycardia [49], and complete heart block [50]. Although there is a temporal association between these reported complications and the

use of flumazenil, other operational criteria used to assess the likelihood of a cause-and-effect relationship were not fulfilled in these cases.

A recent meta-analysis of 13 randomized clinical trials that involved the administration of flumazenil or placebo to patients who had verified or suspected benzodiazepine overdose identified a higher rate of serious adverse effects in patients administered flumazenil. This meta-analysis included studies involving both pure benzodiazepine overdose and polysubstance overdose patients. In this review, 12/498 patients (2.4%) administered flumazenil experienced a serious adverse event, which includes seizures ($n = 3$), arrhythmias ($n = 8$), and hypotension ($n = 1$). In the placebo group, 2/492 patients (<1%) experienced a serious adverse event, both of which were arrhythmias. No patients died. Based on these data, the authors concluded that judicious use of flumazenil is warranted [51].

Despite these studies, other retrospective and prospective studies of undifferentiated acutely poisoned patients who received flumazenil reported a low seizure rate after flumazenil administration [52–56]. While the use of flumazenil in the patient with undiagnosed coma has been reported to obviate the need for further diagnostic studies [52, 54], other data suggest that the use of flumazenil in both pure and mixed benzodiazepine overdoses has not been shown to affect patient outcome, number of procedures, or duration of hospital stay [57] and has also not been shown to be cost-effective [58]. Given the low morbidity and mortality associated with benzodiazepine overdose [59], the benefit gained from flumazenil administration in these patients should be weighed against the potential risk.

The application of flumazenil to clinical settings other than benzodiazepine overdose has also been studied. Lethargy and sedation in patients with hepatic encephalopathy seems to be related, to some extent, to increased levels of endogenous, centrally active benzodiazepine receptor ligands [60] and increased GABAergic tone [61]. Human case reports and studies involving patients with hepatic encephalopathy have reported improved mental status in these patients after the administration of flumazenil [62–65]. The improvement

in mental status after flumazenil administration in these patients is temporary, typically lasting 1–2 h [64, 65]. In a randomized, prospective placebo-controlled study of 527 cirrhotic patients with grade III and IVa hepatic encephalopathy (HE) in which 265 of these patients received flumazenil, 17.5% of those patients with grade III HE and 14.7% of those with grade IVa HE had neurologic improvements compared with 3.8% and 2.7% of the respective HE groups treated with placebo [63]. Administration of flumazenil to a carefully selected group of cirrhotic patients with severe HE may be useful (grade I recommendation), but data are lacking to support the use of flumazenil in all patients with HE. Seizures have not been described following flumazenil use in treatment of hepatic encephalopathy [66]. Flumazenil has also been studied for the potential reversal of ethanol intoxication, and flumazenil administration does not significantly reverse sedation in ethanol-intoxicated patients [67, 68]. Flumazenil has been used to identify those patients undergoing treatment with benzodiazepines for alcohol withdrawal who then develop benzodiazepine-induced delirium; administration of flumazenil to this group improved cognition without resulting in major adverse effects [69].

Contraindications

Absolute contraindications to flumazenil administration include allergies to flumazenil or any components of its formulation. Relative contraindications include the use in patients poisoned by proconvulsant agents, use in patients with benzodiazepine tolerance, and use in patients currently treated for seizures or with a seizure history [38].

Administration

Flumazenil is available as an intravenous preparation. It is formulated as a 5- or 10-mL vial containing 0.1 mg of flumazenil per mL of normal saline and small amounts of methylparaben, propylparaben, edetate disodium, and acetic

acid. Sodium hydroxide, hydrochloric acid, or both are used to adjust the pH of the solution to 7.4.

We recommend that in order to avoid any adverse effects, the smallest effective dose of the drug should be given for reversal of sedation (grade III recommendation). The US Food and Drug Administration approved dosing regimen for reversal of benzodiazepine overdose is 0.2 mg flumazenil administered intravenously over 30 s. If the desired level of consciousness is not attained within 1 min, an additional 0.3 mg may be administered intravenously over 30 s. Repeat doses of 0.5 mg intravenously may be given at 1-min intervals up to a maximum total dose of 3.0 mg. If resedation occurs, additional dosing at 20-min intervals may be given up to a maximum dose of 3 mg in 1 h. For reversal of conscious sedation, flumazenil may be administered at a dose of 0.2 mg intravenously over 15 s. If reversal of sedation does not occur, after 1 min an additional 0.2 mg may be given, and repeated each minute, up to a total dose of 1.0 mg [70]. Following administration and effective use, patients should be monitored for resedation, which can occur 20–120 min after flumazenil administration. If needed, a continuous infusion can be given at 0.3–0.5 mg/h [53].

Folic acid is a water-soluble B-complex vitamin essential for nucleoprotein synthesis, which is necessary for normal growth and development. It traditionally is administered for the treatment of megaloblastic anemias, as for a vitamin supplement or as food fortification due its ability to reduce fetal neural tube defects. Medical toxicologists use folic and folinic acid in the treatment of drug-induced toxicity due to folic acid antagonists and methanol. The focus of this chapter is the use of folic and folinic acids as antidotes.

History of Use

Research in anemias in the early to mid-twentieth century demonstrated that extracts of crude liver had hematopoietic properties and could be used to treat macrocytic anemia [1]. These observations led to the discovery of cyanocobalamin (vitamin B12) and folic acid (vitamin B9), both water-soluble vitamins necessary for the maturation of erythrocytes [2]. Folic acid was first isolated from spinach in the early 1940s and received its name from the word foliage (dark green leaf). Common dietary sources include green leafy vegetables, liver, beans, peas, asparagus, beets, broccoli, and citrus fruits. Subsequent work demonstrated that dietary folate is not metabolically active, but must be converted in vivo to the active tetrahydrofolate (THF) or folinic acid (5-formyl THF) [3].

Folic acid is recognized as a necessary cofactor not only for hematopoiesis but also for normal

growth and development. Periconceptional treatment with multivitamins containing folic acid has reduced the incidence of babies born with neural tube defects, such as spina bifida, encephalocele, and anencephaly [4, 5]. In the United States, the Food and Drug Administration mandated the fortification of enriched grain products with folic acid by 1998, and birth prevalence of neural tube defects is reduced with food fortification of 140 mcg of folic acid per 100 g of grain (approximately 100 mcg to average daily diet) [6]. Most recent data demonstrates approximately 1,326 births which occur annually in the United States without neural tube defects which would otherwise have been affected without this mandate [7].

Folic acid may indeed have non-dietary benefits. Studies from Bangladesh propose folic acid as a treatment for chronic arsenic toxicity. It is thought folic acid administration increases methylation of arsenic, leading to increased arsenic clearance from solid organs in patients who are folic acid deficient and who have chronic arsenic toxicity [8–10]. In addition, folic acid may have a role in preventing bone growth defects in long-term therapeutic methotrexate treatment in children [11, 12].

The ability of leucovorin (folinic acid) to attenuate the toxicity of high-dose methotrexate therapy was first demonstrated in mice in the 1960s [13]. The concept of “leucovorin rescue” is to take advantage of the cytotoxicity of high-dose methotrexate against malignant cells and spare the normal cells from toxic effects [13, 14]. This is discussed in more detail in ► Chap. 60, “Methotrexate.” Leucovorin is also used for the treatment of toxicity from other folate antagonists (trimethoprim, pyrimethamine), but two trials found no benefit, and possibly worse outcomes, in patients with HIV-associated infections [15, 16]. Case reports showing possible benefit of leucovorin treatment in vincristine toxicity have also been published [17, 18]. However, other studies have shown no benefit [19–21].

Commercially available folic acid (pteroylmonoglutamic acid) is prepared synthetically and is used in vitamin supplements (alone or in multivitamin preparations) and in food fortification. Commercial products containing more than

0.4 mg (or 0.8 mg for prenatal use) require a prescription in the United States, as does the parenteral formulation. Folic acid is used in the treatment of megaloblastic and macrocytic anemias that result from folate deficiency.

Folinic acid is commercially available as the calcium salt (leucovorin), and it is marketed primarily as an antidote for the hematologic toxicity of folic acid antagonists such as methotrexate, trimethoprim, or pyrimethamine.

Properties

The term *folic acid* refers to dihydrofolic acid, a B-complex vitamin that in pure form appears as a yellow-orange crystalline powder. It is slightly soluble in water, soluble in dilute alkaline solutions, and insoluble in alcohol. The pharmaceutical folic acid products are prepared synthetically and consist of a central *para*-aminobenzoic acid molecule which is linked to a pteridine ring on one end and a glutamate molecule on the other end (Fig. 1). The molecular formula of folic acid is $C_{18}H_{19}N_7O_6$ (molecular weight, 441.4 g/mol). It is heat sensitive and decomposes rapidly in the presence of light. Dietary folates occur naturally as polyglutamates and must be hydrolyzed (reduced) before absorption [14].

Folinic acid (5-formyltetrahydrofolic acid) is the highly water-soluble product of the reduction of folic acid by the enzyme dihydrofolate reductase (DHFR) (Fig. 2). Its molecular formula is $C_{19}H_{22}N_7O_7$ (molecular weight, 473.4 g/mol). It is commercially available as the calcium salt (leucovorin), a 50% racemic mixture of the *d* and *l* isomers. Only the *l*-isomer (*l*-folinic acid or citrovorum factor) is metabolically active [14].

Pharmacodynamics

Folic acid is an essential vitamin necessary for both nucleoprotein synthesis and the maintenance of normal erythropoiesis (Fig. 3). Folic acid itself is not metabolically active, but rather is activated by reduction and catalyzed by DHFR to 5-methyltetrahydrofolic acid and other

Fig. 1 Chemical structure of folic acid**Fig. 2** Chemical structure of folinic acid

tetrahydrofolate derivatives. Each of the reduced folate congeners can acquire 1-carbon moieties which can be donated in the biosynthesis of nucleic acids, amino acids, proteins, or lipids. Specific reactions (and the specific congener cofactor) in amino acid metabolism which require reduced folic acid coenzymes include the metabolism of homocysteine to methionine (5-methyltetrahydrofolate), the formation of glutamic acid from histidine (tetrahydrofolic acid), and the interconversion of glycine and serine (tetrahydrofolic acid). The methylation of deoxyuridylate to thymidylate, a critical step in the synthesis of DNA, uses 5,10-methylenetetrahydrofolic acid [14]. In folic acid-deficient patients, or patients with inhibited DHFR, a futile cycle of faulty DNA replication occurs leading to clinical effects such as megaloblastic anemias.

Folic acid (as tetrahydrofolate and 10-formyltetrahydrofolate) is also a cofactor necessary for the metabolism of formic acid. Methanol poisoning results in the accumulation of

formic acid in humans. Plasma formic acid concentrations have been shown both in animal models and human case series to correspond closely to the development of metabolic acidosis seen after methanol poisoning [22–26]. The development of metabolic acidosis and depletion of serum bicarbonate, which coincides with the accumulation of formic acid following methanol poisoning, are unique to primates. Other species, such as rats, do not accumulate formic acid and subsequently do not develop metabolic acidosis because of species-specific differences in rates of formic acid oxidation to carbon dioxide, a folate-dependent process [27]. Rats tend to have very high folate stores. The rate of formic acid metabolism and subsequent resolution of metabolic acidosis are decreased during states of folic acid deficiency and increased with folic or folinic acid supplementation in primates [28]. Folic or folinic acid therapy is therefore a component of the treatment of methanol toxicity [29]. This is discussed in greater detail in ► [Chap. 88, “Methanol and Formaldehyde.”](#)

Fig. 3 Folate metabolism. *DHF* folic acid, *NADP* nicotinamide-adenine dinucleotide phosphate, *NADPH* nicotinamide-adenine dinucleotide phosphate, reduced form, *THF* folinic acid (From Ballen KK: Drugs to treat

anemia. In Brody TM, Lamer J, Minneman KP [eds]: Human Pharmacology: Molecular to Clinical, 3rd ed. St. Louis, Mosby, 1998, p 892. – with permission)

Folinic acid is also used in the treatment of methotrexate toxicity [30, 31]. Methotrexate competitively inhibits DHFR and reduces folate formation, which inhibits the biosynthesis of nucleic acids, amino acids, proteins, and lipids (Fig. 4). Clinically, methotrexate toxicity results in a triad of mucositis, renal failure, and myelosuppression [32]. Gastrointestinal signs and symptoms may be pronounced and consist of stomatitis, pharyngitis, anorexia, nausea, emesis, diarrhea, gastrointestinal hemorrhage, and hepatotoxicity. Pancytopenia can develop and may lead to life-threatening bleeding disorders, anemia, and sepsis. Nephrotoxicity can result in oliguria, azotemia, and acute renal failure. This nephrotoxicity may exacerbate systemic toxicity since methotrexate is primarily

Table 1 Summary of pharmacokinetic parameters

	Folic acid	Folinic acid
Absorption	90–100% (synthetic)	97% of 25 mg; 37% of 100 mg
Time to peak serum concentration	30–60 min	1–2 h
Normal serum concentration (total folate)	5–15 ng/ml	
Normal RBC concentration (total folate)	175–316 ng/ml	
Metabolite(s)	5-methyltetrahydrofolate (active)	5-methyltetrahydrofolate (active) L-formyltetrahydrofolate (active) D-formyltetrahydrofolate (inactive)
Excretion (total folate)	Via urine as metabolites Generally complete by 24 h	

eliminated renally. The management of methotrexate toxicity, which is discussed in detail in ► Chap. 60, “Methotrexate,” focuses on administration of folinic acid (leucovorin). Folinic acid must be administered to allow purine and subsequent DNA synthesis to resume. Folic acid administration is not effective because of the methotrexate-induced inhibition of DHFR. Following methotrexate poisoning, intracellular inhibition of DHFR may persist even after methotrexate concentrations are no longer detectable in blood. Most recommendations call for folinic acid administration until signs of systemic toxicity resolve and methotrexate levels are $<0.1 \mu\text{mol/L}$ if methotrexate is being administered for cancer and $<0.01 \mu\text{mol/L}$ if methotrexate is not being administered for cancer (grade III recommendation) [14, 33]. Theoretically folinic acid rescue can also be employed when toxicity occurs from other weaker DHFR inhibitors such as trimethoprim, trimetrexate, pentamidine, and pyrimethamine.

Pharmacokinetics

Reduced dietary folate and pharmaceutical folic acid are absorbed rapidly from the proximal small intestine, including in cases of preexisting malabsorption syndromes. Absorbed folic acid is methylated rapidly by DHFR to active tetrahydrofolate metabolites, including 5-methyltetrahydrofolate, the primary transport and storage form of folate. The active tetrahydrofolates are distributed throughout the body, with highest concentrations

found in the liver (approximately 50% of body stores) and in the cerebrospinal fluid. Urinary recovery of folate is dose-dependent, with only trace amounts of folate found after low doses ($<1 \text{ mg}$) and 90% of folate found in urine after a dose of 15 mg. Excretion is generally complete within 24 h [34].

In contrast to folic acid, leucovorin does not require reduction (activation) and is converted easily to other tetrahydrofolate derivatives. The absorption of leucovorin administered orally becomes saturated with doses greater than 25 mg, making bioavailability dose limited. The *l*-isomer of leucovorin is converted more rapidly to 5-methyltetrahydrofolate when administered orally than when injected. In addition, oral and parenteral doses of leucovorin result in different kinetic profiles for the various metabolites, but these differences are not known to affect efficacy [14, 35]. The inactive *d*-isomer is excreted renally as unchanged drug. The various reduced serum folate metabolites are removed by hemodialysis [14]. Table 1 summarizes the pharmacokinetics of folic and folinic acids.

Special Populations

Neonatal Patients

Recommended dietary allowances of folate are 65 mcg/day and 80 mcg/day for infants 0–6 months and 6–12 months of age, respectively [36]. Folate is distributed in breast milk, and

infant requirements should be met if the mother is healthy and has adequate folic acid intake [34]. There is no published experience with the use of folate as an antidote in neonates, but there should be no reason not to administer folate if necessary in this population.

Pediatric Patients

Recommended dietary allowances of folate are 150–400 mcg/day for children 1–18 years old [36]. There are no special dosing precautions in children who require emergent leucovorin therapy for methotrexate toxicity.

Pregnant Patients

Dietary requirements of folate are highest in pregnant women, particularly those with a history of previous pregnancies complicated by infants with neural tube defects [4, 6]. The recommended dietary allowance in pregnant women is 600 mcg/day [36]. Theoretically, treatment with folate as an antidote for drug toxicity should be particularly aggressive in these patients.

Alcoholic Patients

Malnourished alcoholic patients may have relative deficiencies of all B vitamins, including folic acid [36, 37].

Contraindications

Folic or folinic acid preparations should not be administered to patients with previous hypersensitivity reactions unless clinical circumstances justify the risk. Folic acid and leucovorin should be administered with extreme caution to patients with undifferentiated anemia as folate alleviates hematologic, but not neurologic complications associated with pernicious anemia due to vitamin B₁₂ deficiency [34, 38].

Precautions

Rare cases of allergic reactions to oral and parenteral folic acid have been reported. Clinical manifestations have included erythema, pruritus, rash, and bronchospasm [34]. No deaths have been reported.

Intravenous leucovorin infusions should not exceed 160 mg/min because of the calcium concentration of the solution [38]. Folic acid for injection contains benzyl alcohol as a preservative and should be administered with caution to neonates because a potentially fatal “gasping syndrome” has been associated with benzyl alcohol administration in this age group [39].

Treatment using high-dose methotrexate with leucovorin rescue therapy is best administered only by physicians who are experienced in cancer chemotherapy. Leucovorin may enhance the toxicity of 5-fluorouracil by causing increased inhibition of thymidylate synthase (Fig. 4). In addition, in patients diagnosed with a high-grade malignancy such as a blast crisis from acute leukemia, the disease process may be accelerated if folic or folinic acid alone is administered without antineoplastic therapy [14]. When administering leucovorin rescue following severe overdose, urinary alkalinization is indicated to prevent accumulation of methotrexate in the kidney [33].

Drug Interactions

Several antiepileptic drugs (AEDs), specifically phenytoin, phenobarbital, primidone, and carbamazepine, may result in a lowering of erythrocyte folic acid concentrations. Phenytoin has been the most extensively studied AED demonstrating this interaction, with reports of abnormally low erythrocyte folic acid concentrations in 25% of patients [40, 41]. Conversely, reports of oral folic acid therapy causing a decrease in serum phenytoin concentrations with subsequent breakthrough seizures have been published [41, 42]. Monitoring of AED drug serum concentrations is indicated in patients who subsequently receive folic or folinic acid supplementation.

Adverse Effects

Folic acid administered orally or parenterally is generally well tolerated. Repeated high oral doses (>15 mg/day) may cause nausea, abdominal pain, anorexia, or flatulence. Central nervous system effects associated with high oral doses include irritability, depression, impaired judgment, difficulty in concentration, and altered sleep [34]. Adverse consequences related to folate therapy have not been reported in patients treated for acute methanol poisoning.

Administration

There are no controlled data evaluating the dose and administration of leucovorin calcium and folic acid for acute poisoning of methotrexate and methanol, respectively; however, the selected doses should be administered intravenously in these patients using the guidelines recommended in the methanol and formaldehyde and the Methotrexate chapters.

Folic acid for injection (5 mg/mL) should be diluted with 49 mL of sterile water for injection to a final concentration of 0.1 mg/mL of folic acid and administered by injection over 30 min. Leucovorin calcium powder, after reconstitution with sterile water for injection, should be infused at a rate not exceeding 160 mg/min due to the calcium content of the leucovorin solution [38]. Intrathecal leucovorin is contraindicated due to the calcium content, and it is a neurosurgical emergency if it occurs [33, 43].

Dosing Recommendations in Toxicity

Clinical guidelines recommend that patients with signs of possible methanol poisoning (lethargy, acidosis, and visual disturbances) should be treated with intravenous leucovorin 1 mg/kg up to a maximum dose of 50 mg as soon as possible over 30–60 min, and then the same dose every 4–6 h for six doses, even if the patient's clinical signs resolve [29]. In patients undergoing

hemodialysis, a dose should be given at the conclusion of each dialysis session.

There are case reports of leucovorin therapy for treatment of acute methotrexate ingestion in children [44–46]. The appropriate pediatric dosing of leucovorin is given in ► Chap. 60, “Methotrexate.” Only leucovorin, not folic acid, is effective for methotrexate toxicity or rescue treatment.

For acute intoxication due to trimethoprim or pyrimethamine, 5–15 mg/day of folic acid may be administered orally or parenterally [16, 38].

Summary

- Folic acid or leucovorin is a potential adjunct in the treatment of methanol toxicity.
- Leucovorin rescue (not folic acid) is used in the treatment of methotrexate toxicity.
- If leucovorin is inadvertently administered intrathecally, it is a neurosurgical emergency due to the calcium content.
- Leucovorin should be administered over 10–15 min because of the calcium content.

Fomepizole is the generic drug name for the chemical 4-methylpyrazole (4-MP) now widely available in Europe and North America for the treatment of methanol and ethylene glycol poisoning. It is a potent inhibitor of alcohol dehydrogenase (ADH), with an affinity more than 1000 times that of the toxic alcohols [1]. Fomepizole has demonstrated efficacy *in vivo* against the conversion of methanol and ethylene glycol to their toxic metabolites in animal models [2, 3], where it reversed an already-developed metabolite accumulation and severe metabolic acidosis without dialysis. Because of its high safety profile and ease of use in human patients, fomepizole has rapidly replaced ethanol for ADH-inhibitory therapy in methanol and ethylene glycol poisoning [4]. Fomepizole may also have clinical utility in treating similar intoxications, such as those of glycol ethers, diethylene glycol, and propylene glycol [5–7], as well as in ethanol-disulfiram interactions [8].

Fomepizole was originally developed in Sweden in the late 1960s as one of a series of ADH inhibitors with the potential goal of treating alcohol-related pathologies [1, 9, 10]. In a 1969 paper, in which the chemical 4-MP was shown to be a powerful competitive inhibitor of human liver ADH *in vitro* [1], Li et al. suggested that fomepizole might serve as a clinically useful agent for treating methanol and ethylene glycol poisoning. Subsequently, 4-MP was shown to be useful in the treatment of methanol toxicity in monkeys by McMartin et al. [2], by rapidly reversing the formate accumulation and severe metabolic acidosis [11]. It also reversed ocular signs associated with methanol toxicity, such as the decreased b-wave of the electroretinogram [12]. 4-Methylpyrazole was first shown to be effective at reversing the toxicity of lethal doses of ethylene glycol in monkeys in 1977 [3]. In ethylene glycol-poisoned dogs, a comparison of 4-MP and ethanol treatment was conducted [13]. Although both inhibitors decreased the metabolism of ethylene glycol similarly, fomepizole was superior in clinical usefulness in that ethanol produced a greater degree of CNS depression. Additionally, IV fluid therapy was necessary to maintain hydration in the

ethanol-treated animals. Fomepizole was subsequently confirmed to be therapeutically effective as an antidote in veterinary medicine [14].

Phase I clinical studies of the safety and metabolism of 4-MP in human volunteers have been published [15–18]. Initial case reports of its use in the treatment of ethylene glycol poisoning appeared in 1987 and 1988 [19, 20] and of its use in methanol poisoning appeared in 1997 [21]. Subsequently, a multicenter prospective clinical trial (Phase II/III) was conducted in the USA for the treatment of ethylene glycol [22] and of methanol [23] poisonings. Based on these trials, fomepizole was approved by the US Food and Drug Administration (FDA) for the treatment of ethylene glycol poisoning in 1997 and treatment of methanol poisoning in 2000. Currently, in most of the developed world fomepizole is available for treatment of methanol or ethylene glycol poisoning. It was accepted on the WHO List of Essential Medicines in September 2013 [24], which will likely increase its availability throughout the world.

Properties

Chemical

In the USA, fomepizole is the parenteral preparation of the free-base 4-methylpyrazole with formula $C_4H_6N_2$ (see Fig. 1) and molecular weight of 82.1 g/mol. The free-base form is soluble in both water and ethanol. Fomepizole exists as the hydrochloride salt formulation in Europe and elsewhere.

Fig. 1 Chemical structure of fomepizole

Physical

4-MP base is stable in light and at 4 °C.

Melting point: 16 °C.

Boiling point: 99 °C.

Density: 0.993 g/mL.

λ max: 219 nm.

The parenteral preparation contains 1.5 g per vial and is a slightly yellow liquid that may solidify at room temperature.

Pharmacodynamics

Mechanism of Action

Fomepizole forms a ternary complex with ADH and its coenzyme NAD^+ , thereby competitively inhibiting formation of the enzyme complex with alcohols. The inhibitory constants for fomepizole in vitro with liver ADH from rat, monkey, and human are reported as 1.0, 7.5, and 0.2 μM , respectively [1, 25, 26]. Fomepizole also inhibits the metabolism of methanol by human ADH in vitro [27]. Its initial metabolite 4-hydroxymethylpyrazole (4-OHMP) is also an inhibitor, but is 66-fold less potent, while its secondary metabolite 4-carboxypyrazole (4-CP) has no ADH-inhibitory activity. The affinity of fomepizole for ADH is about 500–1000 times that of ethanol [1, 25], thus about 5000–10,000 times that of methanol or ethylene glycol [27]. Hence, fomepizole substantially competes with either methanol or ethylene glycol, thereby reducing their metabolism by ADH.

In monkeys, fomepizole at 20–50 mg/kg markedly inhibits methanol metabolism [2, 28], thereby eliminating formate accumulation. Studies with 5–15 mg/kg showed that the minimal plasma fomepizole concentration necessary to prevent formate accumulation was 10 $\mu\text{mol/L}$ [28]. In dogs, doses of 5–20 mg/kg were shown to inhibit ethylene glycol metabolism in vivo [13]. In the clinical trials, fomepizole was confirmed to inhibit ethylene glycol elimination in humans in vivo [29]. Subsequent case reports indicate that fomepizole increases the elimination half-life of methanol and ethylene glycol [30, 31].

Other Effects

Acute administration of fomepizole inhibits rat liver cytochrome P-450 activity, especially the isozyme CYP 2E1 (which metabolizes ethanol, acetaminophen, and nitrosamines), however, at much higher doses (100 mg/kg) than necessary to inhibit ADH [32, 33]. The K_i for this inhibition is about 0.5–1 mM or about 1000 times higher than that for liver ADH. Fomepizole inhibits the clearance of P-450-related substrates such as antipyrine in rats [34]. Repeated administration of fomepizole over several days can induce total hepatic cytochrome P-450 activity in rats [35]. Although not all CYP isozymes have been examined, fomepizole can induce CYP 2E1 as well as CYP 2B1/2B2 in rats [36]. As such, fomepizole can increase the oxidation of several different classes of drugs in rats [37], as well as inducing its own metabolism in humans [17, 38]. Other than the study showing auto-induction in humans [38], there are no published studies on interactions of fomepizole on CYP activity or on drug interactions with specific drugs in humans.

Other actions of fomepizole that may be important include its ability to scavenge hydroxyl free radicals [39], to block the disulfiram-ethanol reactions [8], and to protect against the gastric lesions induced by high concentrations of ethanol, probably due to the ability of fomepizole to decrease lipid peroxidation [40].

Pharmacokinetics

Absorption, Distribution, Metabolism, and Elimination

The pharmacokinetic profile of fomepizole is well characterized in animals and humans. Oral fomepizole is rapidly and completely absorbed orally in humans, with doses from 10 to 100 mg/kg producing C_{max} within 2 h and a bioavailability of 1 [16, 38]. Fomepizole is rapidly distributed following IV administration in humans to total body water, with a volume of distribution from 0.59 to 0.74 L/kg. In humans given

equivalent doses of fomepizole either intravenously (IV) or orally [38, 41], plasma fomepizole elimination curves are identical after 30 min, indicating its rapid absorption and distribution. These results suggest that, although fomepizole is marketed as an IV formulation, it should be equally effective if given orally. In dogs, the plasma protein binding of fomepizole is reported to be very low [42]. The renal clearance of unchanged fomepizole is quite low, at about 1 mL/min in human volunteers [16]. Total urinary excretion of fomepizole is only about 3% of the dose in humans and only 1% at similar dose levels in rats [16, 43]. Hence, fomepizole is primarily metabolically eliminated. Fomepizole is metabolized primarily by oxidation to 4-OHMP and then to 4-carboxypyrazole, the latter of which represents > 50% of the dose that is excreted in the urine of humans in 48 h [38]. A minor metabolic pathway appears in rodents to be formation of an N-glucuronide conjugate of fomepizole [44].

Elimination Kinetics

At therapeutic doses (i.e., those producing blood fomepizole concentrations greater than 10 $\mu\text{mol/L}$), fomepizole is eliminated by saturation or nonlinear kinetics. Mayersohn et al. [42] showed that IV doses of 1 and 10 mg/kg in dogs produce a downward curvature of the log-linear plot and an AUC ratio significantly greater than the dose ratio, two indications of saturation kinetics. The apparent zero-order elimination rate at 10 mg/kg was 5 $\mu\text{mol/L/h}$ and an estimate of the Michaelis constant (K_m) was 6 $\mu\text{mol/L}$. In human volunteers, elimination of fomepizole after a single IV dose (5 mg/kg) showed saturation kinetics, with a zero-order rate of 4.2 $\mu\text{mol/L/h}$ and an apparent K_m of about 2.5 $\mu\text{mol/L}$ and V_{max} of 4.2–6.5 $\mu\text{mol/kg/h}$ [18]. Few data exist on fomepizole kinetics in patients being treated for methanol or ethylene glycol poisoning. Nonlinear elimination kinetics have been observed in a methanol-poisoned patient treated with fomepizole (IV, 15 mg/kg) [45] and in an ethylene glycol-poisoned patient (IV, two doses, 8 and 16 mg/kg) [46], with zero-order elimination

rates of 16.9 $\mu\text{mol/kg/h}$ and 7.0 $\mu\text{mol/kg/h}$, respectively, similar to those in the human volunteer studies.

The pharmacokinetic profile of fomepizole after multiple doses such as those used therapeutically has been described in 15 healthy human subjects [38]. Three groups of five subjects were administered oral doses of fomepizole as follows: (1) loading dose of 10 mg/kg, followed by maintenance doses of 3 mg/kg every 12 h up to 96 h, (2) doses of 15 mg/kg plus 5 mg/kg/12 h up to 96 h, and (3) 10 mg/kg plus 5 mg/kg/12 h up to 36 h, then 10 mg/kg/12 h up to 96 h. This multiple-dose study showed that plasma fomepizole concentrations were relatively constant for 36–50 h in groups 1 and 2, after which time the levels markedly decreased. By comparison, the increase in supplemental doses of fomepizole at 36 h in group 3 subjects was sufficient to maintain plasma concentrations of fomepizole within the therapeutic range for 5 days. The elimination rate of fomepizole increased two to threefold within 3 days of multiple dosing, suggesting that plasma levels were unable to be maintained constant in groups 1 and 2 due to the increased fomepizole elimination with repeated dosing. This increase was associated with enhanced urinary excretion of 4-carboxypyrazole, suggesting that elimination of fomepizole increased because of auto-induction of its metabolism. The increase in doses of fomepizole at 36–48 h to overcome the increased elimination and to maintain therapeutic fomepizole concentrations supports the current treatment regimen of increasing the fomepizole dose at 48 h (i.e., typically after the fourth dose).

Some alcohols appear to decrease the elimination of fomepizole, suggesting an interesting mutual inhibition of metabolism. In rats, blood ethanol levels in the range of 350 mg/dL (76 mmol/L) decreased the rate of elimination of fomepizole by 50% [43]. In human volunteers, blood ethanol levels from 50 to 150 mg/dL (11–33 mmol/L) also decreased fomepizole elimination by about 50% [18]. Ethanol did not alter the volume of distribution of fomepizole or the urinary excretion of unchanged fomepizole,

though it did decrease the urinary excretion of 4-CP [18]. These data indicate that ethanol inhibits some step in the conversion of fomepizole to 4-CP. In monkeys, high doses of methanol (2–3 g/kg) increased the rate of fomepizole elimination by 25% [28]. In humans, one could expect that the presence of ethanol or methanol (possibly ethylene glycol, but not studied) will slow the rate of fomepizole elimination because of this interaction.

Dialysis Kinetics

Studies in pigs have demonstrated that fomepizole is readily removed by hemodialysis, with a dialysance of 56 mL/min, similar to that of urea (51 mL/min) [47]. About 20% of the dose was removed during a 4 h dialysis run. Similar dialysis clearance rates have been reported in two ethylene glycol-poisoned patients (52 and 80 mL/min), with somewhat higher rates in two other patients (117 and 127 mL/min) [48, 49]. The extraction rate of fomepizole during intermittent hemodialysis was reported to be 0.78 and 0.71 in two patients [49]. In an unpublished case of ethylene glycol poisoning treated initially with an intermittent, and later with a continuous dialysis modality, the extraction rate of fomepizole was 0.74 during intermittent hemodialysis (HD) and 0.08 during continuous veno-veno HD, indicating that intermittent HD is likely to extract greater amounts of fomepizole than continuous modalities. These studies demonstrate the need to replace the fomepizole that is lost when hemodialysis is conducted on fomepizole-treated patients (see dosing guidelines below).

Clinical Use

We have recently suggested updated treatment criteria for the use of fomepizole for methanol or ethylene glycol poisonings (see Table 1) [50] (Grade III recommendation). The cutoff blood concentrations for the toxic alcohols in the table, which are only for a patient without acidosis or

Table 1 Antidote treatment criteria:^a (Adapted with permission from Ref. [50])

	Recommended criteria
I	Serum ethylene glycol or methanol concentration ≥ 10 mmol/L (62 mg/dL and 32 mg/dL, respectively) ^b
II	Documented/suspected recent history of ingestion with an osmolal gap > 25 mOsm/kg H ₂ O ^c
III	Documented/suspected history of ingestion plus two or more of the following criteria:
	A: Arterial pH < 7.3
	B: Serum bicarbonate < 14 mmol/L or base deficit (BD) > 10 mmol/L
	C: Osmolal gap > 25 mOsm/kg H ₂ O ^c
	D: Presence of urinary oxalate crystals (ethylene glycol only) or visual disturbances (methanol only)

^aAntidote should be given without delay, if toxic alcohol cannot be excluded as the cause. No osmolal gap will be able to exclude toxic alcohol as the cause

^bOnly if there is no significant metabolic acidosis (Base deficit < 10 mmol/L (10 mEq)) or no indications of organ toxicity

^cOG calculated after the ethanol contribution is subtracted

evidence of organ toxicity on admission, reflect the potential *molar levels of toxic metabolite* that could be produced from the alcohol. Hence, the cutoff value of 10 mmol/L (62 mg/dL ethylene glycol, 32 mg/dL methanol) implies 10 mmol/L metabolite maximum, a level that normally does not produce clinical effects [51]. Even so, repeat analysis of acid–base status should be done every 2–4 h to evaluate possible development of acidosis in such patients. Note that patients with blood concentrations < 10 mmol/L, but with clinical signs such as acidosis or organ toxicity, should be treated with fomepizole according to the other criteria in the table.

Use of Fomepizole and Dialysis

Historically, hemodialysis was recommended in fomepizole-treated patients if the plasma methanol or ethylene glycol concentration exceeded 50 mg/dL (16 mmol/L methanol, 8 mmol/L ethylene glycol) or if the patient displayed severe symptoms such as visual loss, severe metabolic

acidosis, or acute kidney injury [4, 52]. However, it has been suggested [52–55], and also shown in a prospective study [56], that fomepizole can postpone or even ameliorate the need for hemodialysis. Also, patients with methanol or ethylene glycol concentrations higher than the above cutoff value have been successfully treated with fomepizole alone, without hemodialysis [30, 31, 56]. In the case of ethylene glycol, dialysis is likely unnecessary in a patient with functional kidneys, because ethylene glycol is renally cleared. Thus, even with ADH inhibition, a substantial portion of the body burden of ethylene glycol can be eliminated by functional kidneys. However, there have been cases with extreme ethylene glycol concentrations (>1000 mg/dL, 161 mmol/L), where dialysis was recommended to avoid any complications related to hyperosmolality [57]. In the case of methanol, initiation of hemodialysis in the presence of fomepizole depends on the condition of the patient and not necessarily on the methanol concentrations per se. Whereas dialysis is an important tool to correct severe metabolic acidosis, a mild or moderate acidosis would easily be corrected by the use of bicarbonate and antidote without providing dialysis. More importantly, a number of hospitals do not have sufficient dialysis capacity available, necessitating antidote therapy as the major treatment approach. Because methanol is primarily cleared by metabolism, such that its half-life during fomepizole therapy is much longer (50–80 h) [30], hemodialysis is often used to eliminate methanol and shorten the duration of fomepizole therapy and number of hospital days [55, 58].

Use of Fomepizole with Diethylene Glycol

Fomepizole has been shown to completely block the acidosis and organ toxicity (liver and kidney) produced by diethylene glycol in rats [59]. Although this suggests that fomepizole is likely efficacious in humans, few cases or outbreaks have utilized fomepizole for treatment. In

one case of diethylene glycol ingestion in a 17-month-old girl, early (6 h) administration of fomepizole, combined with hemodialysis, prevented development of metabolic acidosis and renal dysfunction [60]. A case of combined diethylene glycol and triethylene glycol ingestion by a 15-year-old girl was successfully treated with fomepizole [61]. In contrast, another case of diethylene glycol ingestion was fatal despite treatment with fomepizole [62], likely due to the long delay (>58 h) prior to fomepizole treatment. It is important to note that treatment of diethylene glycol poisoning is not among the FDA-approved uses of fomepizole.

Comparison of Fomepizole and Ethanol

Ethanol also inhibits methanol and ethylene glycol metabolism by competing for ADH activity, making ethanol a suitable alternative to fomepizole under certain circumstances. Both antidotes have a stronger affinity to ADH than the toxic alcohols, with fomepizole binding more strongly (>1000 times that of methanol or ethylene glycol) to the enzyme than ethanol (10–20 times that of methanol or ethylene glycol). Also, fomepizole competitively binds to the enzyme active site, while ethanol itself is metabolized by ADH, thus competing only transiently for the active site. Such characteristics would appear to favor the efficacy of fomepizole; however, there exists no evidence for the superiority of either antidote in terms of the efficacy of the treatment, i.e., in reversal of the toxic alcohol syndromes and survival of patients. The prospective clinical trials of fomepizole [22, 23] did not compare it with ethanol and were not able to distinguish the role of antidote therapy from the role of hemodialysis in producing a favorable outcome. Randomized control trials are lacking. Comparing survival, either prospectively or retrospectively, between different outbreaks is problematic for several methodological reasons: variable reporting of the number of victims and fatalities, uncertain times from ingestion to admission, lack of analytical data, variable toxic alcohol and ethanol concentrations in the ingested substance, and uneven reporting history of ingestion. Despite

Table 2 Ethanol versus fomepizole (Adapted with permission from Ref. [50])

	Ethanol	Fomepizole
Availability	Good (especially orally)	Limited (especially in the developing world)
Cost	Low (in most countries)	High
Practical use	Difficult to keep at therapeutic level, especially during HD	Easy to administer, also during HD
Monitoring of serum concentrations	Necessary	Not necessary
CNS-depressive	Yes	No
Need for HD	Yes	May be avoided or postponed
Need for ICU	Yes	May be avoided

HD hemodialysis, ICU intensive care unit

these caveats, there are two large studies that have attempted to compare the effects of ethanol and fomepizole. Although Paasma and coworkers did not find a significantly better overall outcome with fomepizole, methanol-poisoned patients that could hyperventilate had a significantly better outcome (survival) with fomepizole treatment compared to those treated with ethanol [63]. On the other hand, no difference in outcome between ethanol and fomepizole was found in the study by Zakharov et al. [64], who did a pairwise head-to-head comparison to evaluate the outcome parameters. These patients probably had similar treatment except for the antidote, thus supporting ethanol as an equitable antidote given ideal circumstances. As noted in Table 2 [50], various elements make fomepizole *theoretically* superior to ethanol in terms of *practical* use. A major problem related to ethanol therapy is the difficulty in maintaining recommended plasma concentrations, because ethanol is eliminated more quickly than the methanol or ethylene glycol. There is a huge variability in ethanol elimination rates among humans, and ethanol is rapidly

removed with hemodialysis [65, 66]. To maintain sufficient blood ethanol concentrations, plasma measurements must be frequently performed (every 1–2 h) to make appropriate dosing adjustments.

Another problem associated with ethanol therapy is the potential for adverse effects, most notably, CNS depression. For example, Paasma et al. [67] described a methanol poisoning epidemic in which 40% of the patients who were awake on admission became comatose within 1 h of ethanol treatment. In a retrospective chart review of adverse event reporting in methanol- and ethylene glycol-poisoned cases, CNS symptoms were reported in about half of the cases treated with ethanol, but in only about 2% of those treated with fomepizole [68]. Zakharov et al. reported that 48% of patients treated with ethanol developed severe ethanol intoxication, but did not become comatose, most likely because of the close monitoring of patients receiving ethanol [64].

As noted above, maintaining therapeutic blood ethanol concentrations is difficult and frequently results in overdose, which can lead to CNS depression. In contrast, fomepizole is easy to administer because its pharmacokinetics are predictable with and without dialysis [22, 23, 38, 46]. The dosing schedule (Table 3) is known to maintain therapeutic plasma fomepizole concentrations throughout treatment [16, 52] making monitoring of plasma concentrations unnecessary [69]. Also, in contrast to fomepizole treatment, long-term treatment with ethanol (>24–36 h) may also be complicated by ethanol-induced emotional instability or ill feeling in ethanol-treated patients. These are all elements that would *theoretically* make fomepizole superior to ethanol in terms of treatment.

Combination with Hemodialysis

Fomepizole appears to reduce the need for hemodialysis, particularly in ethylene glycol exposures. Because of the potent ADH binding, well-defined kinetics, and simple dosing scheme of

Table 3 Simplified dosing suggestion for fomepizole treatment for methanol or ethylene glycol poisonings (Adapted with permission from Ref. [50])

		Loading dose	15 mg/kg (Dose 1)	
No dialysis		Maintenance dose	10 mg/kg every 12 h (Dose 2–4)	15 mg/kg every 12 h (Dose 5 onwards)
During dialysis	Intermittent HD	Maintenance dose during IHD	10 mg/kg every 4 h	
		<i>or</i>		
	CVVHD	Maintenance continuous dose during IHD	1 mg/kg/h	
		Maintenance dose during CVVHD	10 mg/kg every 8 h	
		<i>or</i>		
	CVVHD	Maintenance continuous dose during CVVHD	0.5 mg/kg/h	

fomepizole, hemodialysis can be postponed, or even omitted, in some cases if there are limitations in the capacity or availability of dialysis facilities [53, 55, 56, 70]. Due to the difficulty in maintaining therapeutic blood ethanol concentrations, postponing or omitting hemodialysis when the procedure is clinically indicated should be avoided in ethanol-treated patients.

Cost-benefit

The higher acquisition cost has been mentioned as a major disadvantage for fomepizole when compared to ethanol, thus limiting its usefulness in some situations. However, in the USA, the cost of intravenous ethanol and generic fomepizole is now similar [52]. Also for a cost comparison between ethanol and fomepizole, the overall cost-effectiveness must be taken into consideration (including expenses to keep a patient in an ICU, need for nursing care, and need for blood ethanol monitoring with ethanol-treated patients) [71]. The cost of fomepizole acquisition compared to these other expenses largely depends on the country in which the patients are managed and should be taken into consideration with the overall healthcare costs [72]. The cost of fomepizole therapy may be a greater issue with methanol than with ethylene glycol due to the lengthy elimination of methanol during ADH inhibition. However, because of this slow elimination rate of methanol in the ADH-inhibited patient, HD should be performed

if blood methanol concentrations are substantially elevated (see ► Chap. 88, “Methanol and Formaldehyde” for further details).

Special Populations

Children

In the USA, fomepizole has not been officially approved for use in children and no controlled studies in poisoned children have been conducted. Nevertheless, fomepizole has been used in several cases of pediatric toxic alcohol poisoning, with apparently excellent results. In four children, three after ethylene glycol ingestions (from 5 months to 4 years old) and one after methanol ingestion (5 years old), fomepizole treatment was well tolerated and useful therapeutically [73–76]. In two ethylene glycol cases, fomepizole was used successfully without hemodialysis [73, 76].

Pregnant Patients

Fomepizole is considered an FDA Class C drug in the USA, meaning that its effects on reproduction and development have not been adequately determined in animal studies. Studies of fomepizole safety in humans have not been conducted during pregnancy. In pregnant rats, fomepizole readily passes into fetal tissues [77], which would imply significant protection against fetal formation of

toxic alcohol metabolites, thus protecting both mother and fetus. No adverse effects from fomepizole were reported in the dams nor were there any gross abnormalities noticed in the fetuses in this study. Fomepizole has been used to treat one case of methanol poisoning during pregnancy without any reported adverse effects [78]. In a pregnant woman severely poisoned by a metabolically toxic alcohol, an antidote is obligatory – hence, fomepizole should be used, but with care, in pregnant or breast-feeding women.

Contraindications

Fomepizole should not be administered to patients with known hypersensitivity reactions to pyrazole-containing compounds (including celecoxib), although this has yet not been reported to occur in common literature.

Precautions

Fomepizole must be administered IV as a properly diluted formulation (see below) to avoid producing venous irritation. It should also be administered as an IV infusion over 30 min, to allow monitoring for hypersensitivity reactions. Animal studies using high doses (100–200 mg/kg) indicate that acute fomepizole dosing inhibits, while repeated fomepizole dosing (similar to the recommended treatment protocol) induces cytochrome P-450, including CYP 2E1 and possibly 2B1/2B2 [32, 33, 35–37]. Secondly, since fomepizole appears to be metabolized by P-450 [79], other inhibitors of the specific CYP isozyme (currently unknown) may interact with fomepizole metabolism. Hence, physicians should be vigilant of possible drug interactions with fomepizole.

Adverse Effects

The acute LD₅₀ in rodents for fomepizole is 310 mg/kg (IV) and 500–650 mg/kg (oral) [80]. The subacute oral toxicity of fomepizole

has been studied in rats (100 mg/kg for 3 week, then 200 mg/kg for 4th week) and monkeys (100 mg/kg for 5 week, then 200 mg/kg for 6th week) [80, 81]. There was no indication of toxicity in terms of clinical signs, clinical chemical measures, or pathology observed in either species. The plasma fomepizole concentrations in the latter study reached 2000 µmol/L in week six. No visual effects were noted in monkeys treated with fomepizole at 100 mg/kg for 9 days [81]. After a 12-week drinking water exposure in rats, no abnormal liver histology was noted, with plasma fomepizole levels at 85 µmol/L (within the therapeutic range) [82]. At high doses of 400 mg/kg in mice, CNS depression was observed [83].

In the human studies conducted in the 1970s and 1980s, 10 subjects were given oral doses of fomepizole up to 10 mg/kg [10, 84] and 54 subjects were given IV doses of fomepizole at 7 mg/kg [8, 9, 85, 86]. Other than irritation of the peripheral vein in the IV studies, there were no adverse effects reported.

In randomized, blinded, placebo-controlled human volunteer studies, 31 subjects received single oral or intravenous doses in the therapeutic range, with no significant adverse effects reported [15, 17, 18]. During the IV administration, some subjects reported an abnormal smell or taste sensation (the free-base form of fomepizole emits an odor), and venous irritation and transient phlebosclerosis were noted near the site of some injections, but only when the preparation was not suitably diluted. At high single oral doses (50 and 100 mg/kg), six of seven subjects experienced dizziness and nausea, with objective signs (positive Romberg's test) of CNS depression at 100 mg/kg [15]. Despite these effects, vital signs were not affected and clinical chemical and hematologic parameters remained within normal limits in all subjects. In placebo-controlled repeat-dose studies, 15 subjects were treated with oral fomepizole (loading doses of 10–15 mg/kg, maintenance doses of 3–10 mg/kg every 12 h out to 5 days) [17]. Subjective side effects such as nausea, headache, or mild dizziness were reported, but with a similar frequency to those subjects receiving placebo. In some subjects, there was a slight, transient increase in either

serum ALT or AST concentration that resolved by the end of the study and was not dose related, since no subject in the high-dose group was affected.

In the Phase II/III clinical trial, adverse effects of fomepizole were infrequent and minor [22, 23]. Four of 19 patients in the ethylene glycol arm reported effects possibly related to fomepizole, including bradycardia, headache (in two patients), and a seizure after a single dose (but not after subsequent dosing). Six of 11 patients in the methanol arm of the trial reported effects possibly related to fomepizole, including phlebitis, dyspepsia, anxiety, agitation (in two patients), transient tachycardia, and a transient rash in one patient (only after initial doses). Two case summaries have been published from the experience with fomepizole use in treatment of ethylene glycol and methanol poisoning in France [87, 88]. Adverse effects in 11 ethylene glycol-poisoned patients included pain or inflammation at site of injection (two patients), transient eosinophilia (two), and cutaneous eruption, and in 14 methanol patients, fever (two), nausea, headache, and a burning skin sensation.

In a retrospective chart review of 44 patients [68], as well as in a systematic review of published literature up to 2010 [72], the reported adverse effects from the clinical use of fomepizole in methanol- or ethylene glycol-poisoned patients were rare (<2% of patients), consisting of occasional nausea or dizziness and a rare seizure, with uncertain causality.

Administration

The dosing schedule for fomepizole is designed to maintain therapeutic plasma concentrations during the necessary treatment course. Thus, unlike ethanol, no monitoring of plasma fomepizole concentrations is needed to assure efficacy. Fomepizole is available as a parenteral solution that may solidify on storage [89]. It should be slightly warmed to liquefy, then diluted in at least 100 mL of sterile 0.9% sodium chloride or 5% dextrose solution. Dilution and administrations as a 30 min intravenous infusion is important to minimize vessel irritation, as noted above under

Adverse Effects. Diluted solutions remain stable for up to 24 h when stored refrigerated or at room temperature.

Dosing Schedules

The dosing schedule for fomepizole is outlined for patients with and without dialysis in Table 3 [50]. These dosing schedules were used and validated in the two prospective clinical trials of fomepizole in methanol or ethylene glycol poisonings [22, 23]. Fomepizole is cleared readily by hemodialysis as shown in animals [47] and poisoned patients [90]. Therefore, the fomepizole removed by hemodialysis must be replaced. As such, the frequency of maintenance dosing should be increased during intermittent hemodialysis to 4 h intervals; after dialysis, continue the usual 12 h dosing from the time of the last dose during dialysis [91]. Dosing during continuous dialysis modalities can likely be done less frequently, e.g., every 8 h, due to the apparently lower extraction of fomepizole, as noted under **Dialysis Kinetics**. An alternative means to deliver extra fomepizole during dialysis is to give a continuous infusion, with different rates depending on type of dialysis (see table).

Route

An oral preparation of fomepizole is not available in the USA, but is available elsewhere. As described above, Phase I studies indicate that both oral and IV routes of administration produce essentially identical blood concentrations and elimination kinetics.

This chapter describes the administration of specific immunoglobulin antibodies or antibody fragments (IgG, Fab, F(ab')₂, or sFv) to treat toxic exposures. Binding of the antibody to the target molecules or antigen [1] is intended to result in partial or complete neutralization of the toxic effect of the target, a concentration gradient of free target molecules encouraging efflux into the vascular compartment, and ultimate elimination of the antibody/target complex by renal or reticuloendothelial system routes [2–4].

Specific therapeutic antibodies have been developed for cardiac glycosides [5–9], colchicine [10, 11], and phencyclidine [12–14]; paraquat [15–17]; tricyclic antidepressants [18–22]; amantadine [23, 24]; botulinum toxin [25–27]; verapamil [28]; and snake [29–34], scorpion [35–39], spider [40–42], and bee venoms [43, 44]. In the USA, currently approved therapeutic immunoglobulins are available for Crotalinae snake envenomations (Crotalidae polyvalent immune Fab, an ovine Fab; and Anavip, an equine F(ab')₂ that is scheduled to be available in 2018) [Level of evidence(LoE) I], coral snake envenomations (*Micrurus fulvius* antivenom, an equine IgG) [LOE II-3], cardiac glycosides (digoxin immune fab, an ovine Fab) [LoE I], scorpion envenomations (Anascorp, Centruroides (Scorpion) Immune F(ab)₂ (Equine) Injection) [LoE I], and black widow spider envenomations

(*Latrodectus mactans* antivenom, an equine IgG) [LoE II-3]. Antivenoms to nonnative venomous animals often are kept at zoos. In the USA, these are under US Food and Drug Administration (FDA) Investigational New Drug licenses [45], and information regarding these envenomations and antivenoms are available through the online “Antivenom Index” which is accessible by zoos to update contact information and antivenom stocks and poison centers to help coordinate and guide management: (<https://avi.pharmacy.arizona.edu/a/index#top>)

The use of immunotherapies offers the promise of a family of therapeutic immunoglobulins with the ability to bind, neutralize, and eliminate molecules that produce toxic effects without having to devise specific, metabolically based antidotal therapies. The significant pharmacologic, physiologic, and economic challenges of developing heterologous and homologous proteins as antidotes can be seen by the general failure to bring a larger number of these agents to market.

History

One of the first immunoglobulin antivenoms in clinical practice was anti-Crotalidae polyvalent (ACP), an equine IgG, in widespread use in the USA from 1954 until the early 2000s. Based on decades of compelling case experience and experimental data, ACP was effective at stopping the progression of local effects and reversing the systemic effects of Crotalinae envenomations. The occurrences of sometimes severe immediate and delayed hypersensitivity reactions to heterologous whole IgG [37, 46, 47] led to a search for safer alternatives, including F(ab) and F(ab')₂ fragments of IgG, which have largely replaced IgG antivenoms worldwide. In the 1970s and 1980s, it was shown that F(ab')₂ and Fab fragments (Fig. 1) could be produced by enzymatic treatment of IgG, resulting in immunoglobulin fragments that retained binding specificity [48–50]. Because of the removal of the Fc chain and immunoglobulin and other non-target specific proteins by affinity

Fig. 1 Chemical structure of immunoglobulin

purification and other techniques [51], $F(ab')_2$ and Fab fragments were shown generally to have fewer immediate and delayed hypersensitivity reactions than whole IgG [32, 52–55], and it was shown that ovine-derived sera were less likely to result in immediate hypersensitivity reactions than equine-derived sera [32, 33, 54, 56, 57]. $F(ab')_2$ and Fab antivenoms from a variety of source animals have been developed to venoms from snakes, scorpions, and spiders in many countries. Target-specific, single-chain Fv fragments (sFv) (see Fig. 1) have been developed to a variety of agents and have been produced in a variety of host cell lines [6, 16, 58–65]. None of the sFv products are currently used in toxicology and, to our knowledge, there are no commercial products being used as antidotal agents anywhere [66].

Properties

Chemical

IgG is one of a family of structurally-related antibodies. In response to an immunologically recognizable antigen, IgM and ultimately, antigen-specific IgG is produced. IgG has a Y-shape and a molecular weight of approximately 150 kDa. IgG can be subdivided into a Fc and a $F(ab')_2$ regions (see Fig. 1). The Fc chain of amino acids is approximately 50 kDa and the $F(ab')_2$ is 100 kDa. The $F(ab')_2$ regions are responsible for antigen binding [47, 50]. Once the $F(ab')_2$ is bound to an antigen, the Fc chain undergoes a conformational change and is activated [67, 68]. The amino acid sequences in the Fc chain are species specific. Consequently, whole IgG is relatively immunogenic. Depending on the source animal and other factors, it may be complement fixing (the binding of serum complement to the union of an antibody and its target-specific antigen) in humans and cause activations of B-cells [67, 69, 70].

IgG may be cleaved between the Fc chain and the $F(ab')_2$ region, and the Fc component may be eliminated leaving $F(ab')_2$ (Fig. 1). $F(ab')_2$ without Fc chain retains excellent antigen-binding specificity while being less immunogenic. The $F(ab')_2$ fragment may be cleaved further at the

hinge, resulting in two Fab fragments of about 50 kDa each, also retaining antigen-binding specificity [31, 50]. Fab itself comprises three portions, a constant, proximal portion and two variable distal chains covalently linked; the conformational relationships of the portions are responsible for the binding specificity. Elimination of the proximal portion of the Fab results in a single variable-chain Fv fragment of about 25 kDa, which contains the target-specific binding region. In addition, there are associated oligosaccharide moieties that contribute to the conformational structure and binding of immunoglobulins and may vary based on the cell type in which the immunoglobulin is produced, on the culture methods, and on nutrient depletion states; these moieties may be responsible for variability not predicted from studies of protein or DNA sequences alone [68].

Physical

In general, immunoglobulins are concentrated or otherwise purified from the source animal's serum or from a cell line culture. Antivenin polyvalent Crotalidae, *Micrurus* antivenin, CroFab, Digibind, and others are lyophilized, resulting in an off-white pellet that retains binding specificity for years. *Micrurus fulvius* antivenom expiration dates have been extended multiple times by the FDA based on stability testing. Heat may result in denaturation, as do shear forces and polymerization from shaking, foaming, and bubbling that may occur in the process of reconstitution, and lyophilized drug product may also become trapped in foam generated by shaking [71–73]. Reconstitution of lyophilized materials may be optimized by using larger volumes of diluent and manual inversion, which will result in faster mixing times and without loss of purity, protein content, homogeneity, or potency [73].

Pharmacokinetics

Immunoglobulin kinetics is source, recipient, and target dependent, making extrapolation from animal studies difficult and giving each therapeutic

immunoglobulin a relatively unique kinetic and dynamic profile. Kinetics are stable over a wide dose range but may be affected by factors such as source animal, valence (monovalent or polyvalent), route of administration, ionic charge, nonspecific binding, analytical methods, and study design. Individuals display varying kinetics based on renal function and other physiologic parameters (See Table 1). Interaction with the target molecule also can alter the kinetics of the immunoglobulin.

Immunoglobulin kinetic profiles usually fit a two-compartment model with a biexponential curve on a log-linear plot [85]. Generally, the larger the immunoglobulin molecule, the smaller the volume of distribution and the longer the elimination half-life. IgG is distributed to a volume roughly equivalent to the vascular space with a volume of distribution (V_d) < 100 mL/Kg. IgG is eliminated predominantly by the reticuloendothelial system, with a relatively long half-life (approximately 60–194 h) [74, 86]. $F(ab')_2$, Fab, and sFv are distributed to volumes closer to the extracellular volume and are eliminated more rapidly: $F(ab')_2$, 18–133 h; Fab, 15–25 h; sFv, 1.5 h. As their size decreases, proportionate renal elimination increases [74, 86, 87]. Elimination ultimately depends on the size and charge of the unbound immunoglobulin and immunoglobulin/target molecule complex, affecting renal or reticuloendothelial system clearance or both [5, 82, 87]. Interaction between the target molecule and immunoglobulin may affect the target molecule's kinetics, resulting in altered tissue and vascular compartment concentrations [12, 15, 23].

Pharmacodynamics

Clinical efficacy depends on many factors. In general, the immunoglobulin locates and binds to its target and neutralizes its physiologic interaction. Target specificity and binding affinities of immunoglobulins are high (10^8 [8] to 10^{10} [10] M^{-1}) [88, 89] and usually greater than tissue affinities for most drugs. Specific IgG, $F(ab')_2$, Fab, and sFv with similar target specificity and affinity or given in equivalent neutralizing doses should display

similar acute neutralization of a target molecule that is localized in the central circulation or must pass through the central circulation to exert its toxicity [90, 91], excluding half-life differences. Compared with IgG, the larger volumes of distribution of $F(ab')_2$, Fab, and sFv should allow increasing tissue penetration and target binding and neutralization. Mean tissue residence time still may be greater, for IgG than for smaller immunoglobulin fragments, because of its long half-life [87]. In the case of destructive tissue effects from snake envenomation, some venom remains unneutralized, likely in tissue interstices and in the lymphatic system [80, 92, 93]. Unneutralized antivenom may be present likely because immunoglobulin access to the site is limited [94, 95] and appears unrelated to immunoglobulin fraction size or neutralization profiles [70, 96, 97]. Because low-molecular-weight toxins and toxicants may assume the kinetic profiles of their specific antibodies and are redistributed to the vascular compartment or other tissues, if there is only partial neutralization of the target molecules or if immunoglobulin/target dissociation occurs, it may result in increased tissue toxin/toxicant concentrations, variable efficacy, and potentially increased toxicity [12, 15, 17, 23, 24].

Disparity may exist between the half-life of the antigen and specific immunoglobulin, resulting in clearance of unbound immunoglobulin while there still is a body depot of unneutralized target [80, 92, 93]. This situation may result in recurrence of toxicities after most of the unbound immunoglobulin has been eliminated [57, 98]. Degradation of the immunoglobulin may occur, with some $F(ab')_2$ having instability at the hinge region. Conversion of a $F(ab')_2$ to a Fab alters distribution and elimination kinetics, although immunoglobulins seem to retain the ability to bind their targets as long as they are in circulation [5]. Manipulation of cross-linking of sulfhydryl bonds between cysteine residues can increase resistance to degradation of $F(ab')_2$ [99]. Theoretically, the target/immunoglobulin complex may dissociate if it remains in circulation for prolonged periods. A rebound rise of unneutralized digoxin has been reported

Table 1 Human pharmacokinetic parameters of specific IgG, F(ab')₂, and Fab antibodies by IV route^a

Valence abbreviation *M* monovalent, *P* polyvalent

V_{dβ} volume of distribution in the beta phase

posttreatment with digoxin immune Fab, with possible explanations including redistribution of peripheral stores of unneutralized drug and drug-antibody dissociation [5, 100]. Host antibodies targeting the target-specific immunoglobulin (antiidiotypic antibodies) may develop one to several weeks after exposure and may decrease therapeutic immunoglobulin efficacy in subsequent treatments [52, 101]. Because IgG and F(ab')₂ antibodies bind to their targets in a 1:2 M ratio and Fab and sFv bind in a 1:1 ratio, the quantity of target molecules in certain overdoses (e.g., tricyclic antidepressants) may exceed the amount of immunoglobulin that can be given safely or practicably. Clinical efficacy in these circumstances still may be shown if the life-threatening toxicities are abated by partial neutralization of toxin body burdens [22, 34].

In the USA, decades of experience have shown clinical efficacy for immunoglobulin treatment of snake (*Crotalus* and *Micrurus*), scorpion (*Centruroides*), and spider (*Latrodectus*) envenomations and cardiac glycoside poisonings. Because of similarities of venom components across genera, specific antibodies raised to one venomous species often show clinical efficacy against the same genus [40, 47, 102]. Similarly, antidigoxin antibodies show efficacy against other plant and animal cardiac glycosides [7–9] [LoE II-3].

Clinical efficacy of this immunotherapy in humans has yet to be shown convincingly for bee envenomation, colchicine, tricyclic antidepressants, phencyclidine, paraquat, and diquat. Future developments include possibly complexing immunoglobulin fragments with molecules that alter their kinetics and dynamics as well as the use of recombinant DNA technology [66–68, 103–105].

Special Populations

Neonatal and Pediatric Patients

Generally, the dose of immunoglobulin is related to the quantity of target molecules to be neutralized. Children usually receive more

immunoglobulin per body weight than adults, especially for antivenoms [106]. The dose adjustment for body size generally made for pharmaceuticals is not appropriate for immunotherapeutic agents. Attention also should be paid to fluid volumes. Snake antivenom should be reconstituted in a fluid volume of 20 mL/kg with a total to be infused of ≤ 250 mL [LoE I] [45].

Elderly Patients

Unbound sFv and Fab, some F(ab')₂, and immunoglobulin/target complexes of less than 70 kDa are eliminated in part by renal excretion [2, 87, 107]. Impaired renal function results in prolonged half-lives of unbound immunoglobulin and immunoglobulin/target complexes [5, 83, 84]. This situation may prevent or delay recurrence of toxicity by delaying the elimination of unbound immunoglobulin when there is a large disparity between its half-life and that of the target.

Pregnant Patients

Immunoglobulins generally have not been tested in pregnant patients. F(ab')₂ and smaller fragments may cross the placental barrier. The effects of the immunoglobulin and immunoglobulin/target complex on the developing fetus are unknown.

All of the FDA-approved immunoglobulin antibodies are FDA pregnancy category C, which is defined as follows: “Studies have shown that the drug exerts animal teratogenic or embryocidal effects, but there are no controlled studies in women, or no studies are available in either animals or women [LoE II-3]” [108]. These immunoglobulin antibodies in the USA include antivenin (*Crotalidae*) polyvalent (equine; Wyeth-Ayerst, Philadelphia, PA), antivenin *Latrodectus mactans* (equine; Merck & Co, West Point, PA), CroFab (ovine; BTG International, London, UK), and *M. fulvius* antivenin (equine; Wyeth-Ayerst).

Contraindications

Contraindications to the use of therapeutic immunoglobulins include a perceived risk-to-benefit ratio that does not favor treatment. This determination must be made on a case-by-case basis. Because type I (anaphylactic) reactions are common, particularly with whole immunoglobulin preparations, and may be fatal [47, 109–111], indications and contraindications for use have varied [33]. Because of the improved safety profiles of F(ab')₂ and Fab antivenoms, indications for treatment have broadened in recent years [112]. In some cases, because of the rapidity of onset of respiratory paralysis with eastern coral snake envenomations, for example, it has been recommended that antivenom be given before signs and symptoms appear [47, 113]. Special caution should be used when administering immunoglobulin treatment to patients with a history of prior immediate hypersensitivity reactions to that antivenom or to the serum of the source animal, although such patients have been treated successfully with antivenom [114–116]. Multiple doses of immunoglobulin antibodies have been given without the development of type 1 hypersensitivity reactions [LoE II-3] [117].

Precautions

Type I hypersensitivity reactions are immediately occurring reactions to an antigenic stimulus, usually because specific immunoglobulins to that antigen were produced during a previous exposure. Anaphylactic reactions can occur with immunoglobulins, particularly as they involve nonhuman source animals. IgE-mediated hypersensitivity reactions may be fatal [109, 111]. Anaphylactoid (non-IgE-mediated type I hypersensitivity) reactions often are related to the infusion rate. ► Chapter 26, “Toxicant-Induced Immunological Reactions” reviews management of type 1 hypersensitivity reactions. These are discussed in greater detail in the chapter on immunologic reactions.

Skin tests are recommended by the manufacturers of ACP, *Micrurus*, and *Latrodectus* antivenoms as a way to test for the patient's risk of developing a type I hypersensitivity reaction. Skin testing is controversial but for most modern antivenoms, the sensitivity and specificity of skin tests to predict subsequent hypersensitivity reactions are insufficiently sensitive and insufficiently specific to rely on for clinical decision-making [LoE II-2] [33, 47]. The initial dose of antivenom given in a location has the capability to manage allergic reactions [LoE III]. Pretreatment with H₁- and H₂-receptor blockers may be considered in patients considered at high risk (e.g., a history of allergy or atopy) [LoE II-3] [47]. In general, smaller immunoglobulin fragments have fewer and milder reports of type I reactions. Reports of the incidence of type I reactions to various IgGs have ranged from 8% to 87% and to various Fab and F(ab')₂ immunoglobulins from 6.3% to 20% [47, 118]. In one large study, type I reactions to ACP in Crotalinae envenomations were reported in 23% of cases, with half of them severe reactions [109]. In contrast, type I reactions to CroFab, a Crotalinae ovine Fab, were reported in 19% of cases, with two thirds of them mild, one third moderate, and none severe [57]. Because venom and other toxins can cause type I hypersensitivity reaction, the trigger may not be clear [119]. When the trigger is unclear, timing of onset of symptoms versus timing of administration may be helpful.

Type III (delayed) hypersensitivity reactions (serum sickness) may occur 1 day to 3 weeks after treatment with an immunoglobulin. Type III reactions result from the formation of circulating immunoglobulin/target complexes, usually in the context of antigen excess and associated with complement activation [120]. These complexes are deposited in endothelial cells in vessels, where they produce widespread vascular injury and complement activation. Clinical effects of type III reactions are persistent urticaria, arthralgias, myalgias, angioedema, swollen lymph nodes, vomiting, and fever [47, 109]. Type III reactions typically are seen much more frequently and are more severe with IgG snake antivenoms than with other antivenoms [47]; this is thought to

reflect the higher doses associated with treatment of snakebites and the relatively greater immunogenic reactivity of whole IgG preparations, which may predispose to vascular injury. The incidence of type III reactions after equine IgG has been reported to be 15–86% with ACP [33, 47] and 61% with *Centruroides* antivenom [37]. CroFab had an incidence of type III reactions of 13% [57, 121].

Recurrence Phenomena

A phenomenon of recurrent toxicity (recurrence of toxicity after initial reversal or stabilization) has been reported in patients treated with therapeutic immunoglobulins and is believed to be the result of disparities in the pharmacokinetics and pharmacodynamics between the target and its specific immunoglobulin [93]. In the treatment of Crotalinae envenomations with a Fab antivenom, local symptoms may recur in 50% of patients after initial control with antivenom. Coagulopathy (abnormal platelet counts, fibrinogen, prothrombin time, and activated thromboplastin time) may recur in 69% of patients after initial control with the antivenom [57, 122]. The mechanisms of recurrence are believed to be a kinetic disparity between the half-life of venom components and unbound immunoglobulin and a dynamic disparity in which not all venom is neutralized initially. This situation allows local injury to recur when protective serum levels are lost at the interface between normal tissue and the local venom depot and likewise allows coagulopathy to recur when unneutralized venom from a depot reenters the vascular compartment after protective Fab concentrations have been lost [57]. Coagulopathy recurrence with ACP, an equine IgG, usually mild and subclinical but occasionally severe, also has been reported and is likely due to the same mechanism [98, 122, 123]. Local recurrence with Fab antivenom, consistent with the time course of local injury [124], typically occurs within the first 24 h [57, 124]. Because coagulopathy recurrence likely results from recurrence of venom antigenemia from a depot of unneutralized

venom, it is similar in kind and degree to the presenting coagulopathy, is typically seen 2–4 days after treatment, and may persist for more than 2 weeks [57, 92, 123]. Predictors of either recurrent or late, new-onset hematologic effects include early hematologic abnormalities or indicators such as elevated d-dimers indicating fibrinogenolysis and an increase in platelets following antivenom administration indicating platelet-active venom factors [125].

A similar recurrence phenomenon has been reported with digoxin toxicity treated with an ovine Fab. Recurrence of free digoxin concentrations usually occurs 12–24 h after initial treatment and may be due to redistribution of unneutralized, peripheral stores of the drug or possibly to drug-antibody dissociation. In patients with renal failure, this recurrence may occur within a few hours of treatment [100] or be delayed 12–130 h [5]. Other kinetic and dynamic mismatches between targets and target-specific immunoglobulins may result in decreased therapeutic benefit or other adverse effects.

Treatment of Adverse Effects

Anaphylactic and anaphylactoid reactions should be treated in the standard manner. If an immunoglobulin is being given intravenously and is suspected of being the cause of the reaction, the infusion should be stopped. Epinephrine, H₁- and H₂-blockers, and corticosteroids should be given as indicated. The treatment of anaphylaxis is discussed in detail in the chapter on immunologic reactions. The decision to restart the infusion in severe reactions should be made on the basis of the risk-to-benefit ratio to the patient. If the infusion is restarted, consideration should be given to diluting the infusion further and restarting it slowly to avoid an anaphylactoid reaction. It is uncertain, however, whether the incidence of severe type I reactions can be reduced by slower infusion (LoE II-3) [45, 126]. Simultaneous infusion of antivenom along with intravenous epinephrine may be instituted and maintained cautiously if the patient is showing signs of an

Fig. 2 Monitoring for coagulopathy in patients treated with Crotalidae polyvalent immune Fab (ovine) (From Boyer et al. [131])

anaphylactic reaction, but it still is deemed clinically essential that the patient receive the antivenom [LoE III-3] [114, 115, 119, 127].

Late hypersensitivity reactions (serum sickness) usually produce pruritic and sometimes painful urticaria or purpuric skin rashes. Mild reactions may be treated with H₁- and H₂-blockers and nonsteroidal antiinflammatory agents. For moderate-to-severe symptoms, corticosteroids have been recommended [LoE II-3] [37, 128]. Although patients have been reported to improve after these medications [109, 128], no controlled studies have firmly established their utility. Some patients may require readmission for symptomatic care [109].

Prevention of recurrence of local effects in ovine Fab-treated Crotalinae envenomation can be accomplished by following the initial control of local symptoms with additional scheduled doses of antivenom (two vials of antivenom every 6 h for three additional doses) [LoE II-1] [57]. Although it is theoretically possible to

prevent coagulopathy recurrences by maintaining a constant protective level of antivenom [80], no such studies have been performed. The need for and efficacy of late use of antivenom in these cases are uncertain [122]. Although the risk of spontaneous bleeding from recurrent coagulopathy is considered small, there almost certainly is an increased risk with surgery or trauma in patients with low platelet counts or fibrinogen [122]. Recommendations for posttreatment monitoring of Fab-treated patients and for consideration of retreatment with antivenom are presented in Fig. 2 and Table 2. [LoE II-2] [122]. Continuous IV infusion of antivenom has been used for severe recurrent or late, new-onset hematologic effects and better matches antivenom and venom kinetics, although it requires in-hospital management [LoE II-3] [129]. Similarly, significant recurrence of toxic effects from digoxin toxicity after treatment with ovine Fab may be retreated with additional digoxin-specific Fab [LoE II-2] [5], Table 2.

Table 2 Recommendations for indications for retreatment of recurrent coagulopathy with FabAV

Fibrinogen <50 µg/mL
Platelet count <25,000/mm
INR >3.0
APTT >50 s
Multicomponent coagulopathy
Worsening trend in patient with prior severe coagulopathy
High-risk behavior for trauma
Comorbid conditions that increase hemorrhagic risk

From Boyer et al. [131]

The phrase lipid resuscitation therapy (LRT) refers to the intravenous administration of an emulsion, typically containing approximately 20% lipid, for the management of poisonings. Originally developed for the treatment of local anesthetic cardiovascular toxicity, the use of LRT has extended to the management, or attempt at management, of a multitude of other poisonings.

In 1974 Kriegelstein et al. demonstrated that lipid administration acts as a large reservoir for the drug chlorpromazine [1]. However, the concept of LRT for local anesthetic toxicity has its roots in a study by Weinberg et al. (1998) [2] in which it was demonstrated that rats can be resuscitated from bupivacaine-induced cardiac arrest by the administration of a large of dose lipid emulsion. In this study 7.5 cc/kg of a 30% lipid emulsion was given as a bolus post-arrest, followed by 3 cc/kg/min for 2 min. The LD₅₀ for bupivacaine if treated with lipid emulsion was 18.5 mg/kg. In contrast, in rats treated with an equivalent volume of saline, it was statistically significantly lower at 12.5 mg/kg [2].

Further impetus for the use of LRT for local anesthetic poisoning came from a very dramatic finding [3] in a canine model of bupivacaine-induced cardiac arrest. In this study dogs in cardiac arrest were given 10 min of open chest cardiopulmonary resuscitation at which time they were randomized to a 20% lipid emulsion or an equivalent volume of normal saline, given as a 4 cc/kg bolus followed by 0.5 cc/kg/min for

10 min. Reportedly, 100% (6/6) dogs were successfully resuscitated in the LRT group; none of the six dogs in the saline group survived the arrest.

The first published use of LRT in human toxicity described a 58-year-old male with a known history of exertional angina and an electrocardiogram (ECG) showing a right bundle branch block, a left anterior hemiblock, and an old anterior myocardial infarction, undergoing arthroscopic rotator cuff repair. Described as awake and alert during the bupivacaine infusion, 30 s later he had the first of two generalized clonic tonic seizures followed by an asystolic cardiac arrest. Advanced cardiac life support (ACLS) consisting of intubation, chest compressions, epinephrine, atropine, amiodarone, and arginine vasopressin failed to provide return of spontaneous circulation (ROSC). Consequently, after 20 min of unsuccessful resuscitation using standard medications, the patient received 100 mL of 10% ILE followed by an infusion of 0.5 cc/kg/min through a peripheral IV line. Fifteen seconds after the bolus, he achieved ROSC with normal sinus rhythm and was ultimately discharged neurologically intact [4].

Also in 2006, Litz et al. [5] reported a case of an 84-year-old female with a left bundle branch block and mitral and tricuspid regurgitation who accidentally received 50 cc of 1%, instead of the intended 0.5%, ropivacaine for the repair of a Dupuytren's contracture. The ropivacaine administration was followed by an asystolic cardiac arrest which was managed with 10 min of ACLS, including three 1 mg epinephrine boluses. Because of a lack of response, 100 mL of 20% lipid emulsion was administered, followed by a 10 cc/min infusion (0.2 cc/kg/min). After a total of approximately 200 cc, she achieved ROSC and had a complete recovery and no evidence of myocardial injury.

Following these, and other sometimes less dramatic, reports, considerable enthusiasm has emerged about the potential utility of LRT in the treatment of cardiovascular and, to a lesser extent, neurological toxicity from a variety of poisonings. Most of the published subsequent literature has been in the form of anecdotal case reports and controlled animal studies, the latter done with

various degrees of rigor. Although some case reports continue to describe sometimes dramatic feats of survival following LRT, their significance is limited by certain publication bias, given that only successfully resuscitated patients are likely to be the subjects of reports deemed publishable by journal editors. Lipid resuscitation therapy is currently widely attempted, even if still non-validated under real-world clinical conditions. While its role, if any, is still being elucidated, many medical toxicologists view it as a reasonable measure for patients *in extremis*, or in actual cardiac arrest, given the possibility of benefit. Current American Heart Association ACLS recommendations are [6]:

1. "It may be reasonable to administer ILE (Intravenous lipid emulsion), concomitant with standard resuscitative care, to patients with local anesthetic toxicity and particularly to patients who have premonitory neurotoxicity or cardiac arrest due to bupivacaine toxicity"; and,
2. "It may be reasonable to administer ILE to patients with other forms of drug toxicity who are failing standard resuscitative measures."

A systematic review sponsored by six major clinical toxicology societies worldwide (three from the USA and one each from Canada, the Asia-Pacific region, and Europe) concluded that the quality of evidence for the use of LRT in nonlocal anesthetic poisoning is low to very low [7].

Given the widespread use of LRT, the impressive anecdotes describing its victories, particularly in cases of local anesthetic toxicity, and the possible benefit that may accrue from its use, this chapter on the clinical pharmacology of LRT is included in this text. A discussion of the potential, role, if any, for LRT in the treatment of specific poisonings is discussed in the various toxicant-specific chapters. Table 1 lists drugs for which LRT has been utilized.

Properties

Lipid emulsions designed for pharmaceutical use are formulated as a source of calories and lipids for patients receiving parenteral nutrition. These preparations vary between countries. For

example, in the USA the most frequent product used is Intralipid^R a 20% emulsion composed of 10% soybean oil, 1.2% egg yolk phospholipids, and 2.25% glycerin and other bioactive substances such as vitamin K and phytoestrogens [8]. There are other products in various countries, such as Liposyn III^R, Nutrilipid^R, SMOFlipid^R, ClinOleic^R, and Lipoven^R. Most of these preparations contain 10 or 20% soybean oil.

Pharmacodynamics

The actual mechanism by which LRT may act is illusive. The two main mechanisms that have been postulated are partitioning of lipid-soluble drugs into an iatrogenically lipophilic serum fraction, hence causing an efflux from peripheral targets (the “lipid sink” theory), and enhancing cardiac fatty acid metabolism and mitochondrial respiration. The latter is predicated on the fact that the heart preferentially utilizes fatty acids for approximately 70% of its energy generation, the balance from glucose and pyruvate oxidation [9].

The lipid sink model is supported by several reports that serum drug concentrations increase after LRT [7]. However, this is not universally the case, suggesting that this is either not the mechanism of action of LRT or that it exerts more than one mechanism [7, 10]. In an in vitro model, Weinberg et al. (2006) [11] demonstrated that a lipid infusion accelerates removal of bupivacaine from the rat heart and that this is correlated with recovery of markers of cardiotoxicity. The degree of induced serum lipophilicity necessary to produce a partitioning effect is a matter of controversy. Clearly, this will vary with the partition coefficient of the drug (or other chemical substances) under physiological conditions, its degree of protein binding, and its volume of distribution. However, at the present state of our understanding of LRT, there are few data that can be relied on to tailor the specific LRT infusion to a specific drug or other target molecules. Fettiplace and Weinberg [12] have argued that a 1% serum lipid concentration is sufficient to generate a partitioning effect for molecules likely to be influenced by lipophilicity. Their rationale

for this is the calculated lipid fraction of serum necessary to produce a partitioning effect in two human volunteer studies [10, 13] and porcine models demonstrating partitioning of amiodarone and amitriptyline [12].

Further support for the lipid sink mechanism comes from a study on isolated verapamil-poisoned cardiomyocytes, in which verapamil binding to the L-type calcium channel inhibited the inward calcium current and myocyte shortening [14]. Incubation with ILE in serum caused a flux of verapamil into the serum compartment and restored both the calcium current and myocyte shortening. The sequestration of verapamil into the serum increased in a dose-dependent manner between 0.03 and 2.5 vol.%. Visual inspection of their data suggests that any further increase in serum lipid concentration did not appear to have a significant effect. One percent lipid in serum sequestered 70% of the added verapamil. The concentration of lipid at the completion of an ILE infusion has been estimated at 1.6 volume percent [14].

The cardiostimulatory theory finds considerable support in both in vivo [10] and in vitro models where direct effects on cardiac function can be assessed in the absence of any lipid sink effect [15, 16]. It has shown that a 1% plasma lipid concentration in crystalloid produced a cardiostimulatory effect in a Langendorff model of a perfused rat heart. A similar computerized physiologically based pharmacokinetic model predicted that the major effect of ILE on the bupivacaine toxic rat heart Langendorff model was primarily cardiostimulatory [17]. However, an in vivo porcine model of bupivacaine toxicity failed to find any significant enhancement of myocardial respiration from LRT. This is in marked contrast to in vitro studies with isolated bupivacaine-poisoned mitochondria [10]. However, the difference between in vitro and in vivo studies likely derives from the non-physiological conditions in the former. The in vitro study by Kryshtal et al. (2015) [14] described above found no increase in cardiomyocyte calcium currents when incubated with serum containing lipid emulsion in the absence of verapamil.

A third proposed mechanism for LRT is that it raises blood pressure due to vasoconstriction in

the absence of enhancing cardiac function. A porcine study showed substantial increases in mean arterial pressure when ILE was administered either alone or after a bupivacaine infusion without a concomitant effect on myocardial bioenergetics [10]. This vasotonic effect may be secondary to enhancing α_1 -adrenoreceptor tone. An effect on the α_1 -receptor, or its downstream mechanism, is supported by both human volunteer [18–20] and in vitro studies [10]. The α_1 -receptor is G-protein linked, with further stimulation of phospholipase C leading to activation of protein kinase C and subsequent vasoconstriction. Protein kinase C is stimulated by unsaturated fatty acids such as oleic acid, a constituent of Intralipid^R. Similarly, an ILE infusion of only 40 cc/h in human volunteers has been shown to modestly increase blood pressure [10, 21, 22]. However, a study on nonpoisoned rats found that ILE administration increases blood pressure and aortic flow in the absence of a significant effect on peripheral vascular resistance [15].

A fourth postulated mechanism of action of LRT derives from the observation that ILE may inhibit endothelial nitric oxide synthase (e-NOS), thus decreasing nitric oxide-induced vasodilatation [23]. Unsaturated fatty acids are direct inhibitors of e-NOS [24, 25]. However, support for this mechanism, based on current knowledge, is weak. Lastly, some advocate that ILE may work via altering calcium levels in the heart. In vitro studies have demonstrated free fatty acids can open voltage-gated calcium channels in myocardial cells. Those who believe the change in calcium theory argue the associated increase in intracellular calcium after ILE may be desirable in drug-induced myocardial depression [26].

Pharmacokinetics

The pharmacokinetics of ILE is only partially understood. In human volunteers administered lipid emulsion lipid clearance from serum was a first-order process [27]. In a case of verapamil poisoning successfully treated with LRT, the serum triglyceride concentration fell with an approximately 3 h half-life [28].

Contraindications

Lipid resuscitation therapy is obviously contraindicated in patients with an allergy to soybean oil, unless it is felt that the patient was in extremis and unlikely to survive without it. In patients that have active pancreatitis, a history of chronic pancreatitis or severe hypertriglyceridemia there is a theoretical risk of causing or exacerbating pancreatitis (Grade III evidence).

Administration

The American College of Medical Toxicology (ACMT) has recommended an ILE infusion protocol [29] that is a minor modification of that initially put forth by the UK Resuscitation Council. The Association of Anesthetists of Great Britain and Ireland and the web site LipidRescue.org have also suggested similar infusion regimens. The ACMT recommended regimen (Grade II-3 evidence) calls for the initial infusion of 20% ILE as a 1.5 cc/kg bolus over 2–3 min. This can be administered by drawing the desired volume of 20% lipid emulsion into 50 cc syringes. The bolus can be followed by an infusion of 0.25 cc/kg/min. For asystolic patients, or those with pulseless electrical activity, the dose can be repeated. Unless absolutely necessary, the infusion should be stopped after an hour (Grade III recommendation). This amounts to 1,890 ccs for a 70 kg patient. Fettiplace et al. has warned that exceeding this amount may predispose to potential adverse effects [12] and has suggested a more conservative protocol of a 1.5 cc/kg loading dose and 0.225 cc/kg (or roughly 150 cc in a 70 kg person) over 3 min, followed by an infusion of 0.025 cc/kg/min (or approximately 100 cc/h in a 70 kg person) for up to 6.5 h (Grade III recommendation). None of these infusion regimens have been empirically tested or compared. Based on our current state of knowledge, for the patient in extremis or in cardiac arrest, it seems more sensible to use the more aggressive regimen such as that proposed by the ACMT (Grade III recommendation). For more stable patients, the Fettiplace protocol may be preferred; however,

there is no clear rationale for using LRT in relatively stable patients.

Adverse Effects

Theoretically, the potential complications of LRT relate to lipid overload, which could manifest as acute pancreatitis and the acute respiratory distress syndrome. Other obvious theoretical concerns are lipid interference with extracorporeal circuits used for cardiorespiratory support on substance removal and laboratory studies. The extent to which these complications occur with LRT is unknown.

A recent systematic review of adverse effects associated with LRT assessed cardiovascular, hematological, renal, metabolic, pulmonary, allergic, vascular, pancreatic, and inflammatory effects as well as effects on extracorporeal circuits [30]. That review considered 114 publications, 24% of which were controlled animal studies. Assessment of study quality was by the GRADE criteria [31]. Most publications were found to be of low quality. Potential adverse effects of lipid therapy identified were acute kidney injury, cardiac arrest, ventilation/perfusion mismatch, acute respiratory distress syndrome, venous thromboembolism, hypersensitivity, fat embolism, fat overload syndrome, pancreatitis, extracorporeal circuit obstruction, and allergic reactions (Grade III evidence). With the exception of allergic reactions, these adverse effects appeared to be dose dependent. Nevertheless, the degree to which any of these obtain cannot be determined from the available data, and it is likely that some are conflated with the actual condition being treated.

Interference with laboratory testing by hypertriglyceridemia is well known and can occur in patients treated with ILE [32]. Serum lipid concentrations that are sufficiently high to cause separation of the serum into a lipid-rich supernatant and an aqueous infranatant can cause partitioning of analytes such that the results may not accurately reflect their concentration in the patient's circulation. Even in the absence of such partitioning, light scattering by high lipid concentrations can cause an analytical error. The

degree to which these errors occur will vary with the lipid concentration and technique used, so are effectively unpredictable.

Analytical errors caused by hyperlipidemia may be remedied by centrifugation [33] after which the lipemic supernatant can be removed by gentle aspiration. It has been suggested that approximately two thirds of the remaining infranatant serum can be transferred to a clean tube using a glass pipette prior to analysis in order to achieve a more valid assay [33]. This extra processing can be time consuming and can result in substantial delays before analytical results are available [32]. Nonetheless, despite performing such a process, laboratory interference can persist.

Lipid emulsions may contain a variety of ingredients, depending on the manufacturer and formulation. Potential adverse events may depend on the specific formulation used. For example, for soybean oil and egg yolk phospholipid-based ILE, such as Intralipid^R, it is possible that individuals with either soybean or egg allergy may have immunological reactions to lipid emulsion administration. However, if these allergies are to soy or egg proteins, it seems unlikely that an allergic reaction will ensue. Nevertheless, before administering ILE to a patient with one of these allergies, appropriate precautions, such as an established epinephrine infusion, are warranted (Grade III recommendation). Given that many patients are in extremis when they receive their lipid therapy, they may already have such an infusion established.

Methylene blue was one of the first antimalarial agents to be used clinically. It was also used as an intestinal and urinary antiseptic since the nineteenth century [1]. Since that time, methylene blue has mostly been abandoned for these clinical indications owing to the discovery of much more effective agents. Today, however, methylene blue continues to be a component of certain medications, used to treat urinary tract infections, including Atrosept, Dolsed, UAA, Uridon modified, Urised, Uritin, and Prosed/DS. (Trade names given here are examples from those used in the USA. They may vary between countries.) Methylene blue also has many nontoxicologic medical uses. A major use of methylene blue by clinical toxicologists is in the treatment of methemoglobinemia, a condition discussed in detail in ► Chap. 30, “Toxicant-Induced Hematologic Syndromes.” Methylene blue was reported to have been administered as an antidote in the USA 149 times in 2013 (116 in patients over 20 years old) by US poison centers [2]. Its use has been increasing; methylene blue was reported to be administered 105 and 85 times in the USA in 1999 and 2000, respectively. It is likely that these data represented a fraction of its total antidotal use.

Nontoxicologic Medical Uses for Methylene Blue

Urinary tract infections, antiseptic [1], antimalarial agent [1]

Nasolacrimal duct patency [3]

Topical ophthalmic medication [4]

Detection of cerebrospinal fluid leaks after intrathecal administration [5]

Detection of enteroperitoneal fistulas [6]

Evaluation of fallopian tube patency after cervical administration [7, 8]

Component of cancer chemotherapeutic regimens [9–15]

Histochemical staining reagent [16]

Priapism treatment [17]

Viral inactivation [18–25]

Treatment for septic shock [26]

Management of condylomata acuminata [27]

Reduction of intraperitoneal surgical adhesions [28]

Treatment of hepatopulmonary syndrome [29]

Inhibition of postintervention restenosis of vessels [30]

Use in multiple indicator dilution studies of in situ pulmonary endothelium [31]

Multidrug-resistant reverser in cells [32]

Component of protein solder for vascular anastomoses [33]

Intraoperative parathyroid gland identification [34]

Targeting of melanomas [35]

Supravital stain [36]

Detection of parturient leakage in the presence of twins after intra-amniotic infusion (rarely used) [37–50]

Treatment of distributive shock [51–56]

Antimicrobial photosensitizers (photodynamic therapy) [57]

Distributive shock [58]

Recurrent laryngeal nerve identification during thyroidectomy [59]

Intravital staining in parotidectomies [60]

Reduction of pain following lumbar open discectomies [61]

Improved lymph node harvest in rectal CA specimens [62]

History

Before its use in the treatment of methemoglobinemia, methylene blue was used as an antidote for cyanide and carbon monoxide poisoning. After the studies of Sahlin in 1926 and Eddy in the early 1930s as reported by Hanzlik [63], Geiger [64] was the first to use methylene blue clinically as an antidote for cyanide poisoning. Geiger, the director of public health in San Francisco, reported the demise of three patients from cyanide poisoning treated with supportive care only. A fourth patient, following an attempted suicide by potassium cyanide ingestion, was resuscitated successfully, however, using 50 mL of 1% methylene blue solution. At the same time, numerous cases of the successful treatment of patients with carbon monoxide poisoning with methylene blue were reported [65–67]. Today, more effective and appropriate therapies are available for carbon monoxide and cyanide poisoning.

The first reported case showing the use of methylene blue to treat methemoglobinemia was by Williams and Challis [68], who described their treatment of a male university student exposed to *para*-bromoaniline who presented with a skin color of “mauve lavender.” Spectrophotometric evaluation confirmed the disappearance of methemoglobin from the blood after treatment with methylene blue. Animal experimentation with two rabbits by these authors, published in conjunction with this case report, showed that 5–6 mg/kg of a 1% methylene blue solution was effective in treating methemoglobinemia. The reported patient was treated with 1000 mg of methylene blue as an intravenous 1% solution. Williams and Challis [68] chose to use methylene blue in their reported case and animal studies because of the previous literature suggesting the utility of this dye in cyanide and carbon monoxide poisoning. Steele and Spink [69] reported a similar reversal of methemoglobinemia in two cases, one aniline induced and the other caused by acetanilide intoxication, after the administration of methylene blue at a dose of approximately 4 mg/kg. The reversal of methemoglobinemia by methylene blue reported by these authors did not elicit enthusiasm because it was thought of as the

antidote for cyanide toxicity. In addition, there were reports that warned of the potential problem of methylene blue paradoxically inducing methemoglobinemia [70–72].

Nadler and colleagues [73] examined the possible induction of methemoglobinemia by intravenous methylene blue (50 mL of 1% solution) administered to 18 healthy adult volunteers. This was the same dose reported by Geiger to be effective in the treatment of his cyanide-poisoned patient. Assuming that the volunteers weighed 50–70 kg, this would constitute a 5–7 mg/kg dose of methylene blue. Neither Geiger nor Nadler provided the actual weights of the patient or volunteers treated; however, a letter to the editor of the *Journal of the American Medical Association* by Bodansky [74] in 1950 stated that the dose was approximately 7 mg/kg. Nadler and colleagues [73] showed that in their volunteers methemoglobin concentrations never exceeded 1.3 g/dL and that the side effects, including electrocardiogram changes, “a sense of oppression in the chest,” dysuria, nausea, and blue discoloration of the skin and mucous membranes, were due not to the presence of methemoglobin, but rather to the direct effects of the dye itself.

Wendel [75], who had shown that methylene blue’s mode of action in cyanide toxicity derived from its ability to form methemoglobin, initially expressed disbelief in the ability of methylene blue to reduce the concentrations of methemoglobin in the blood. However, his own later studies in dogs with sulfanilamide-induced methemoglobinemia showed that intravenous administration of methylene blue at 5 mg/kg would increase the normal conversion rate of methemoglobin to hemoglobin by eight- to tenfold, and a dose of only 1 mg/kg intravenously would increase this rate three- to fourfold [76]. Gutmann and coworkers [77] later elucidated the mechanism by which methylene blue reduces methemoglobin levels.

Further refinement of the dosage of methylene blue required for the treatment of methemoglobinemia arose from the work of Hartmann and colleagues [78]. This was a case series of six patients, ranging from 3.5–11 years of age, admitted to the hospital with an infection and treated with

sulfanilamide. Four patients developed methemoglobinemia, which was treated successfully with methylene blue at doses of 1–2 mg/kg intravenously or 65–130 mg/day orally (3.8–4.7 mg/kg/dose; 18.9–23.9 mg/kg/day). Two of the six children were given methylene blue orally concomitant with the sulfanilamide administration and had no methemoglobinemia. This series suggested that elevated methemoglobin concentrations could be treated successfully with a methylene blue dose of 1–2 mg/kg and that the higher doses administered in earlier studies were unnecessary. Additional reported cases of methemoglobinemia confirmed the safety and efficacy of intravenous methylene blue administered at 1–2 mg/kg [79–81].

Etteldorf [82] reported eight premature infants, ages 6–26 days, all of whom developed methemoglobinemia after being placed in new cloth diapers with the name of the hospital recently stamped on them with an aniline-containing ink. Seven of the eight infants were discovered to be neurologically depressed, with cyanosis of the nail beds and mucous membranes and with methemoglobin concentrations ranging from 10% to 60%. These infants received methylene blue intravenously at a dose of 1.5 mg/kg (0.1% via a scalp vein). All had clinical responses within 15–30 min, simultaneous with the resolution of the methemoglobinemia. Strauch and colleagues [83] published a report of the development of methemoglobinemia in a 2-year-old girl with burns over 50% of her body after treatment with topical 0.5% silver nitrate. Her methemoglobin concentration of 59% and clinical findings resolved 15–30 min after the initiation of intravenous methylene blue at a dose of 2 mg/kg. Wendel [75] reported that dogs with sodium nitrite-induced methemoglobinemia responded rapidly to the intravenous administration of 2 mg/kg of methylene blue, which also reportedly increased the rate of conversion of methemoglobin to hemoglobin by four to fivefold. This report also described 100 cyanotic patients receiving sulfanilamide; 90 of these had methemoglobin concentrations of greater than 3%, and 35 had methemoglobin levels of 15–40%. The administration of 1–2 mg/kg of intravenous methylene

blue to these patients was associated with rapid clinical improvement and resolution of methemoglobinemia [84].

Based on the above, the generally recommended dose of methylene blue for the treatment of methemoglobinemia is 1–2 mg/kg intravenously. Continuous intravenous administration of methylene blue, in doses ranging from 0.1 mg/kg/h for 96 h to 3–7 mg/kg/h for 7 days, has been reported in the treatment of dapsone intoxication. Acute Heinz body hemolytic anemia, as a result of either the dapsone or the methylene blue treatment, was reported in both patients. Until further evidence of its safety and efficacy can be attained, methylene blue therapy via continuous intravenous administration is not recommended [85, 86].

Properties

Chemical

Methylene blue (Fig. 1), with its polycyclic, planar ring structure, is a chromophore possessing the ability to absorb photons (λ_{max} 665 nm) with consequent transformation to a short-lived excited state. The chromophore character of methylene blue is essential for the important role this cationic dye assumes in the treatment of methemoglobinemia because it allows the molecule to accept electrons from the nicotinamide adenine dinucleotide phosphate (reduced form) (NADPH-dependent methemoglobin reductase) and subsequently donate them to methemoglobin with the resultant reduction back to hemoglobin. This same characteristic is also the basis of the methylene blue-associated phototoxicity reactions that have been noted in neonates having been exposed to it

Fig. 1 Chemical structure of methylene blue (tetramethyl thionine chloride)

intra-amniotically and who then were placed under phototherapy lights for hyperbilirubinemia [37, 38].

Physical

Methylene blue, tetramethyl thionine chloride (anhydrous form, CAS (Chemical Abstracts Service number) no. 61-73-4; trihydrate form, CAS no. 7220-79-3), is a water-soluble and alcohol-soluble compound with a molecular weight of 373.90 g/mol and a maximum absorption at wavelength of 665 nm. First prepared by Caro in 1876, this compound now is usually prepared from dimethylaniline and thiosulfuric acid. The trihydrate form usually is found as dark green crystals with a bronze-like luster and a slight odor or as a crystalline powder.

Pharmacodynamics

Methylene blue's role in the treatment of methemoglobinemia arises from its ability to interact with methemoglobin and specific enzyme systems within the erythrocyte. Even in the absence of any additional chemically induced oxidative stress, the hemoglobin within the red blood cells (RBCs) slowly tends to oxidize in the presence of normal concentrations of oxygen. The enzyme system responsible for the endogenous reduction of methemoglobin to hemoglobin is NADH-dependent cytochrome-*b*₅ reductase, which actually consists of the cytochrome *b*₅ and the flavin-containing cytochrome-*b*₅ reductase (Fig. 2) [87, 88]. This is a first-order process that occurs at a rate of approximately 15% of total methemoglobin per hour. Under normal circumstances, this enzyme system is capable of maintaining the methemoglobin concentration at less than 1% of the total hemoglobin [89]. The reducing agent NADH is a normal product of glycolysis (see Fig. 2) and acts as an electron source to reduce cytochrome-*b*₅ reductase. This reduced enzyme acts as an electron donor for oxidized cytochrome *b*₅. The now-reduced cytochrome *b*₅ reduces the ferric (Fe^{3+}) iron of methemoglobin to the ferrous (Fe^{2+})

Fig. 2 Predominant pathway for endogenous methemoglobin (*MetHb*) reduction. *NADH* nicotinamide adenine dinucleotide (reduced form)

form, generating hemoglobin. In the presence of a sufficient exogenous oxidative stress, the amount of methemoglobin formed may exceed the reducing capacity of this cytochrome-*b*₅ reductase system, resulting in methemoglobinemia.

A second enzyme system within the RBC, the NADPH-dependent methemoglobin reductase, normally has a minimal role in the reduction of methemoglobin (Fig. 3). Under usual conditions, the absence of this system or its activity does not result in clinical methemoglobinemia [88, 90]. This enzyme system, which apparently usually functions to reduce exogenous substances other than methemoglobin, in the presence of methylene blue can enhance the reduction of methemoglobin to hemoglobin [77, 91, 92]. NADPH, produced by the hexose monophosphate shunt, reduces NADPH-dependent methemoglobin reductase, an enzyme that has an affinity for methylene blue, among other dyes, and reduces methylene blue to the form leukomethylene blue,

which has a high affinity for methemoglobin (see Fig. 3). The leukomethylene blue reduces the ferric (Fe^{3+}) iron of methemoglobin, forming hemoglobin. The NADPH-dependent methemoglobin reductase, which under usual conditions is responsible for less than 5% of the reduction of methemoglobin to hemoglobin, assumes a major role in the pharmacotherapy of methemoglobinemia. Oxidation of hemoglobin to methemoglobin can occur at high doses of methylene blue due to a reversal of the NADPH-dependent methemoglobin reductase pathway.

Pharmacokinetics

After developing a spectrophotometric assay to measure methylene blue and leukomethylene blue in blood, urine, and tissues, DiSanto and Wagner [93–95] examined the pharmacokinetics of methylene blue in humans, dogs, and rats. In a

Fig. 3 Minor pathway for methemoglobin (*MetHb*) reduction, which is increased in the presence of methylene blue. *NADP* nicotinamide adenine dinucleotide phosphate, *NADPH* nicotinamide adenine dinucleotide phosphate (reduced form)

study of seven adult male volunteers who received 10 mg of methylene blue orally, with subsequent urinary methylene blue determinations for 120 h, 74% (range 53–97%) of the administered material was recovered; 78% (range 65–85%) in the leukomethylene blue form was recovered, showing that methylene blue is well absorbed orally in humans. In the same study, two dogs (one female and one male) received methylene blue orally, with blood concentrations assayed in both animals and urine concentrations assayed in one animal. After receiving 15 mg/kg of methylene blue orally, the male dog had undetectable blood methylene blue 6.9 h after administration. No urine was sampled from this animal. The female dog received 15 mg/kg of methylene blue orally, with urine sampled every hour for 10 h. Only 2.4% of the methylene blue was excreted in the urine over 10 h. This same female dog also received a total of 10 mg of methylene blue orally

followed by methylene blue measurements in the blood at 2.5 and 3.5 h and in the urine every hour for 14 h after the administration. Only 3.8% of the methylene blue was recovered in the urine, and essentially undetectable levels of methylene blue were reported in the blood. The authors concluded that in contrast to humans, dogs have poor gastrointestinal absorption of methylene blue.

Pharmacokinetics of Methylene Blue

Volume of distribution (Vd): 0.222–0.876 L/kg

pKa: 0 to –1

Clearance (CL): 1.98–2.65 L/kg/h

Half-life (T_{1/2}): 5–6.5 h

Time of maximal concentration (T_{max}): 1–2 h

In a second study by the same authors, one dog was administered each of five doses of methylene blue (2–15 mg/kg) at least 2–3 weeks apart

followed by measurement of the compound in the blood. A semilog plot revealed a biexponential relationship between blood concentration of methylene blue and time after administration, which was consistent with a linear two-compartment open model. The data also were well fitted to the nonlinear single-compartment model, however, with even less variability noted in the volumes of distribution, elimination rate constants, and clearance rates. Using the linear two-compartment model, the average volume of distribution was found to be 0.876 L/kg, with a plasma clearance rate of 2.65 L/kg/h. The nonlinear one-compartment model yielded an average volume of distribution of 0.222 L/kg, with a plasma clearance rate of 1.98 L/kg/h.

In rat studies of intravenous administration of methylene blue, six doses ranging from 2 to 25 mg/kg were given, and methylene blue was measured spectrophotometrically in the blood, lungs, liver, kidney, and heart after the rats were killed 3 min after the injection. An average of 29.8% (range 25.3–35.8%) of the administered dose of methylene blue was present in the four tissues 3 min after intravenous administration. This finding provided support to the nonlinear one-compartment model. The pharmacokinetics of methylene blue after oral and intravenous administration also has been studied in humans [96]. After the administration of 100 mg of methylene blue via either the oral or the parenteral route in seven human volunteers, the time course of methylene blue in the blood was measured by high-performance liquid chromatography, and the urinary excretion was determined spectrophotometrically. After oral administration, the maximal methylene blue blood concentration was reached at 1–2 h, with the levels being an order of magnitude lower than that attained after intravenous administration of the same dose. The time course displayed by methylene blue blood concentrations after intravenous administration was multiphasic, requiring an equation containing three exponential terms to fit the data. The urinary excretion of methylene blue at 24 h was approximately 28% and 18% after intravenous and oral

administration, respectively, with one third excreted as leukomethylene blue. The half-life of methylene blue was calculated to be 5–6.5 h.

These same authors studied the organ distribution of methylene blue after oral and intravenous administration in eight rats. One hour after the administration of 10 mg/kg of methylene blue intravenously or intraduodenally, the animals were killed, and the distribution of methylene blue into the blood, brain, intestinal wall, liver, and bile was measured by high-performance liquid chromatography. These studies revealed that greater than 97% of the dose administered intraduodenally was absorbed in this period. Little methylene blue could be detected in the blood 1 h after intraduodenal administration compared with the significantly higher level after intravenous administration; however, there was a 50-fold greater concentration of methylene blue in the intestinal wall after intraduodenal administration than that measured after intravenous administration. The authors offer this “first pass distribution” as the explanation for the order-of-magnitude difference in the methylene blue blood concentrations and area under the concentration curve found after intravenous and intraduodenal administration. As a result of the experimental differences noted between species and within the same species, as attested to by previous studies in humans, dogs, and rats, the pharmacokinetic profile of methylene blue requires further elucidation.

Special Populations

Neonatal Patients

Neonates, especially premature ones, are expected to be more vulnerable to the formation of methemoglobin and to the development of side effects from methylene blue therapy if appropriate doses are not used. Neonates may be more vulnerable to the oxidative stresses of the environment for the following reasons: (1) NADH-dependent methemoglobin reductase activity or levels or both are not fully acquired until age 3–6 months (perhaps longer in premature infants) [97–100];

(2) although this idea is controversial, the fetal hemoglobin may be oxidized more readily into methemoglobin than the adult type [101, 102]; and (3) the skin of infants (especially premature infants) is much more permeable to some external toxicants than the skin of children or adults. Heinz body hemolytic anemia has been noted in premature infants in whom methylene blue was instilled to ensure proper placement of a nasojunal tube [103].

Exposure of an infant during intra-amniotic infusion of methylene blue to determine prepartum leakage or the presence of twins may result in methemoglobinemia, acute hemolytic anemia with Heinz body formation, hyperbilirubinemia, photosensitization of the skin with subsequent desquamation in the newborn, and possibly intestinal obstruction [37–50]. Goluboff and Wheaton first reported methylene blue-induced hemolytic anemia in the treatment of methemoglobinemia in an infant [104]. The doses used were excessive, however, a total of > 26 mg/kg in one infant and > 35 mg/kg in the second infant. Many reports showed that newborn infants, including premature ones, with methemoglobinemia from an intoxicant may be treated safely with intravenous methylene blue at a dose of 1–2 mg/kg without adverse effects (level of evidence [LoE]III) [79–82]. The 1–2 mg/kg dose may not be required, however. Hjelt and colleagues [105] treated 13 infants with a mean gestational age of 28 weeks and birth weight average of 895 g with methylene blue for methemoglobinemia. In these neonates, intoxicated via the skin and respiratory tract by parachloraniline produced by the heating of chlorhexidine, the mean methemoglobin concentration was 19% (range 6.5–45.5%). Intravenous methylene blue administered at a dose of 0.3–0.9 mg/kg was found to be as effective as the 1–1.6 mg/kg initially used in this group. In the treatment of neonates with methemoglobinemia, a lower dose of intravenous methylene blue may be effective. A problem commonly encountered in small infants is intravenous access. Methylene blue at a dose of 1 mg/kg administered by the intraosseous route over 3–5 min has been shown to be effective in the

treatment of methemoglobinemia in a 6-week-old infant without adverse effects [106].

Glucose-6-Phosphate Dehydrogenase Deficiency

Glucose-6-phosphate dehydrogenase (G6PD) deficiency is an X-linked disorder that results in an altered primary structure of G6PD with a subsequent reduction in the enzyme's functional activity [90, 107]. A male with the disorder or a female homozygous for the mutant gene would be expected to express the defect fully. Numerous variants of this enzyme deficiency exist. The African type, the G6PD A variant, is estimated to be present in approximately 11% of African Americans. The G6PD activity level within the erythrocyte of unaffected individuals normally decreases as the RBCs age. An accelerated rate of activity loss is seen in the African type of G6PD, with only 10% residual activity present mostly in the younger RBCs. An even greater rate of loss is found in the Mediterranean type of the deficiency, which may be present in 2.5–25% of that population [108, 109]. Heinz body hemolytic anemias and methemoglobinemias may be produced by the administration of methylene blue to patients with G6PD deficiency [7, 110, 111]. An absence of G6PD, the first enzyme in the hexose monophosphate shunt pathway, results in the absence of NADPH production within the RBCs. Without NADPH, the RBC is unable to reduce methylene blue to leukomethylene blue. The resultant proportionately higher levels of the electron acceptor (oxidizing agent) methylene blue may produce hemolysis and, paradoxically, methemoglobinemia in the G6PD-deficient patient.

Methylene blue administered to a G6PD-deficient patient with methemoglobinemia would not be expected to be effective because of the absence of sufficient NADPH. However, a G6PD-deficient patient may possess only a partial deficiency of the enzyme. This is true especially in a heterozygous female, who may possess nearly normal activity levels and display some lowering

of methemoglobin levels after methylene blue therapy [112, 113]. Methylene blue administration remains the first-line therapy for methemoglobinemia, even in G6PD-deficient individuals. If the recommended dose of 1–2 mg/kg of intravenous methylene blue does not produce a response in these individuals, additional doses of methylene blue should be avoided owing to the possibility of escalating further the already elevated levels of methemoglobin and inducing a hemolytic anemia.

Other Patients

Patients not expected to respond to methylene blue include those with sulfhemoglobinemia, fully expressed G6PD deficiency (X-linked), NADPH-dependent methemoglobin reductase deficiency [114], NADH-dependent cytochrome-*b*₅ reductase deficiency (autosomal recessive) [115], cytochrome-*b*₅ deficiency (autosomal recessive) [116], and hemoglobin M (autosomal dominant) [117]. Patients already treated with excessive doses of methylene blue who have developed methemoglobinemia may experience an escalation of methemoglobin concentration with further methylene blue administration. Lastly, patients poisoned with an overwhelming amount of intoxicants or poisons characterized by continual gastrointestinal absorption or metabolite formation may seem not to respond to methylene blue.

Methylene blue has been used as adjunctive therapy in toxicities and overdoses other than methemoglobin producers. Through its ability to inhibit nitric oxide synthase (along with scavenging nitric oxide), it has been reported to have been used successfully in treating refractory distributive shock due to atenolol/amlodipine overdose along with mixed valproate, carbamazepine, quetiapine, and fluoxetine overdose (LoE III) [52–56, 118]. In the latter case, a loading dose of 1.5 mg/kg and continuous infusion of 1.5 mg/kg for 12 h followed by 0.75 mg/kg for 12 h resulted in rapid improvement in blood pressure [53].

Methylene blue has also been used to treat refractory shock from anaphylaxis with most

case reports involving protamine or radiocontrast as the offending agent [54].

N-Acetylcysteine (NAC) was originally marketed in 1963 as Mucomyst[®] [1] for inhalation use as a mucolytic due to its ability to break disulfide bonds in mucoprotein complexes in chronic bronchopulmonary disease [2]. It was then studied as an antidote for acetaminophen (paracetamol; APAP) poisoning in the 1970s and since then has been the standard of care for treatment of APAP toxicity. NAC has also been investigated as an antidote for many other toxicants [3–13].

In 1973, Mitchell and coworkers described the metabolism of acetaminophen (see Fig. 2 of ► Chap. 59, “Acetaminophen/Paracetamol”) and postulated that acute toxicity of this drug was related to the bioactivation of acetaminophen to a chemically reactive arylating agent [14]. With therapeutic doses of acetaminophen, this highly reactive intermediate (later discovered to be *N*-acetyl-*p*-benzoquinone imine [15]) is conjugated by glutathione, which prevents tissue damage. When hepatic glutathione stores are depleted to 10–30% of normal stores, the reactive intermediate binds to hepatocyte proteins, initiating a cascade of events leading to hepatocellular necrosis [16]. Recent studies question the role of this binding in the pathogenesis of the hepatic necrosis and postulate a large role for the downstream mechanism of oxidative stress [17, 18]. Nevertheless, this earlier discovery led to a search for agents that could modify the metabolism of acetaminophen or interrupt the binding of the toxic metabolite to liver cells. Agents such as cysteamine and methionine were tried with varying

degrees of success [19–21]. While screening potential antidotes in mice, Piperno and Berssenbruegge showed that doses of NAC of up to 1,200 mg provided protection from hepatotoxicity against a fatal dose of 1,500 mg/kg of acetaminophen [22].

Before this experiment, NAC, sold in the United States and elsewhere under the brand name of Mucomyst[®], had been used by inhalation as an adjunct in the removal of abnormally thick, excessive mucus secretions from the lungs. Rumack and Peterson obtained a New Drug Application from the US Food and Drug Administration (FDA) in 1976 to study the effectiveness of the oral administration of NAC in the management of acetaminophen poisoning and in 1978 reported the successful treatment of the first 416 patients [23]. At the same time, the efficacy of intravenous NAC was under investigation by Prescott in the United Kingdom, with the results reported in 1977 [24]. In 1985, NAC received FDA approval for the 72-h oral treatment of acetaminophen poisoning supported by the results of the US National Multicenter Study [25]. Extensive use of NAC in the treatment of acetaminophen poisoning worldwide since the publication of these studies resulted in it being the standard of care in the treatment of APAP poisoning. In 2004, NAC received FDA approval for intravenous use under the brand name of Acetadote[®] [26].

Although not as well studied as in the treatment of acetaminophen poisoning, NAC also has been advocated in the treatment of mercury toxicity [3, 4], carbon tetrachloride hepatotoxicity [5, 6], gold toxicity [7], arsenic toxicity [8], zinc chloride smoke inhalation [9], and *Amanita phalloides* mushroom poisoning [10, 11] as well as to reduce the adverse effects of many cancer chemotherapy drugs [12, 13]. The enthusiasm for the free

radical-scavenging properties of NAC has extended into the treatment of non-toxicology-related critical illnesses, such as septic shock [27], coronary artery disease [28], hepatic failure of any cause [29–31], respiratory distress syndrome [32], abdominal aortic aneurysm repair [33], necrotizing enterocolitis [34], and sickle cell disease [35]. Oral NAC administration has also been studied in the prevention of contrast-induced nephropathy, but several studies failed to show superiority to hydration or other treatments, such as sodium bicarbonate or ascorbic acid [36–42]. In addition, NAC has been promoted as a dietary supplement; it is marketed as a free radical scavenger capable of enhancing immune function, specifically for prevention of colds and influenza and as an adjunct to mainstream therapy for patients with human immunodeficiency virus infection and chronic lung disease [43]. Recent studies also report better recovery following NAC administration after intensive exercise training [44].

Chemical Properties

The chemical structure of NAC is shown in Fig. 1. Other chemical names synonymous with NAC are *N*-acetyl-L-cysteine, L- α -acetamido- β -mercaptopropionic acid, and *N*-acetyl-3-mercaptoalanine.

Physical Properties

The molecular weight of NAC is 163.2 g/mol. It is a crystalline solid at room temperature with a melting point of 110 °F (43 °C). It has a strong, disagreeable, sulfur-esque “rotten egg” odor [45].

Pharmacodynamics

The precise mechanism through which NAC protects from acute acetaminophen toxicity is not entirely known. However, several possible mechanisms have been proposed. First, NAC is deacetylated to cysteine, which can be incorporated into the synthesis of glutathione, raising the intracellular concentration of reduced glutathione

[46]. Second, the availability of cysteine seems to be the rate-limiting step in the synthesis of glutathione, and NAC administration replenishes depleted supplies. Alternatively, NAC may act as a glutathione substitute, providing thiol groups to bind *N*-acetyl-*p*-benzoquinone imine, or encourage the reduction of this metabolite back to acetaminophen, thus sparing hepatocytes [47]. However, animal experiments failed to show that NAC formed significant amounts of conjugate with the reactive metabolite of acetaminophen [48, 49]. In one model, NAC provided a source of sulfate, reduced *N*-acetyl-*p*-benzoquinone imine back to acetaminophen, and increased the synthesis of glutathione [48]. Lastly, new animal findings suggest that the role of NAC in acetaminophen overdose might be more than related to its metabolism itself and could also involve recovery of mitochondrial glutathione levels and support of the mitochondrial bioenergetics [50].

In acute acetaminophen poisoning, NAC, if given within 8 h of ingestion, is highly effective [25, 51] (Grade II-2). Beyond 8 h, efficacy declines with the amount of time during which NAPQI can be produced and subsequently cause hepatotoxicity [25]. However, as demonstrated in randomized clinical trials in selected patients who developed fulminant hepatic failure admitted to a liver unit, the rate of survival was significantly higher in the NAC-treated group even with a delay from ingestion to treatment of more than 50 h [52, 53] (Grade I). NAC may be effective at modulating the cascade of inflammation that occurs in hepatic necrosis, limiting further injury to unaffected liver cells. It also has been postulated that NAC increases hepatic and cerebral microvascular blood flow in patients with liver failure [29]. The efficacy of NAC in acetaminophen poisoning is discussed in more depth in ► Chap. 59, “Acetaminophen/Paracetamol.”

Pharmacokinetics

The pharmacokinetic profile of NAC is difficult to study because the drug exists in the plasma in a multitude of forms – oxidized, reduced, and protein bound. Analytical techniques may detect some but not all of the forms, making comparisons between studies impossible [54].

Oral absorption of NAC seems to be rapid, with peak blood concentrations occurring at 30–90 min after ingestion [55, 56]. The bioavailability of oral NAC may be as little as 10% because of significant first-pass extraction or metabolism by the liver [57]. With such a large first-pass effect with a possible enhancement of portal circulation by direct delivery to the liver and the fact that the target organ of acetaminophen is the liver, the clinical relevance of this low bioavailability explains the manyfold safety margins that were calculated when the dosing schedule for the PO regimen to treat APAP toxicity was proposed. The volume of distribution of unchanged NAC has been estimated to be 0.3–0.5 L/kg [56, 57]. Metabolism of NAC is extensive, with the following oxidized metabolic products found in the plasma: *N,N'*-diacetylcysteine, *N*-acetylcysteine cysteine, *N*-acetylcysteine protein, and *N*-acetylcysteine glutathione. The major metabolic products after complete metabolism are cysteine, cystine, inorganic sulfate, and glutathione [57].

After an intravenous loading dose of 150 mg/kg administered over 15 min, peak plasma NAC concentrations averaged 554 mg/L. Using the 20-h intravenous NAC protocol described by Prescott (150 mg/kg loading dose, followed by 50 mg/kg for 4 h, followed by 100 mg/kg for 16 h), a mean steady-state concentration of 35 mg/L (range 10–90 mg/L) was achieved at 12 h [58]. North and colleagues reported peak NAC plasma levels of 9.3–16.2 µg/mL after the oral administration of 140 mg/kg of NAC [55].

Controversy exists over the effect of concurrently administered oral activated charcoal on the bioavailability of oral NAC. Ekins and coworkers, using 19 healthy volunteers, reported a 39% reduction in the oral absorption of NAC when immediately followed by a 100-g dose of activated charcoal [59]. North et al. reported no decrease in peak plasma NAC concentrations or area under the curve and a slight delay in time to peak when 50 g of oral activated charcoal was given 15 min before a 140-mg/kg oral dose of NAC in three healthy volunteers [55]. Renzi et al. found similar results in six volunteers given activated charcoal and NAC in the same fashion as in the other study [60]. None of these

three studies considered the total amount of NAC that must be supplied to prevent acetaminophen-induced cell injury effectively [55, 59, 60]. Because the oral dose of NAC used (140 mg/kg loading dose followed by 17 doses of 70 mg/kg every 4 h) seems to be effective for even large acetaminophen overdoses, there is an apparent “margin of safety” built into the total dose.

There is preliminary evidence that the pharmacokinetics of NAC may be altered in patients with severe hepatic injury. The pharmacokinetic profile of NAC was compared in nine biopsy-proven cirrhotic patients and compared with six controls [61]. In the patients with cirrhosis, the area under the serum concentration versus time curve was nearly double (152.3 vs. 93.9 mg/L/h) following administration of 600 mg intravenously compared with controls given the same dose. This was mainly due to decreased clearance. NAC has not been formally studied for potential teratogenic effects in humans and is listed as FDA pregnancy category B (animal reproduction studies have failed to demonstrate a risk to the fetus, and there are no adequate and well-controlled studies in pregnant women or animal studies have shown an adverse effect, but adequate and well-controlled studies in pregnant women have failed to demonstrate a risk to the fetus in any trimester). There is greater risk associated with withholding NAC treatment in pregnant women with acute acetaminophen poisoning (Grade III). Although few cases have been reported, deaths of the mother and fetus have occurred when NAC treatment was either withheld or delayed [62, 63]. NAC concentrations in the cord blood of infants whose mothers are being treated with NAC were shown to be equal to concentrations seen in adults being treated with NAC [64]. When 300 pregnant women with acetaminophen overdose were studied, in which 33 were treated with *N*-acetylcysteine, only 17 patients had acetaminophen concentrations greater than or equal to 100 mg/L at 4 h (661 μ mol/L). Twelve pregnancies ended with normal infants, three were electively terminated, and two were spontaneously aborted [65].

Adverse Effects and Contraindications

Oral NAC is generally well tolerated and considered an extremely safe treatment. As a result of the strong rotten egg odor and the gastrointestinal upset commonly seen after acetaminophen overdose, vomiting is the most common side effect observed with oral NAC. In fact, in one study, 51% of 515 acetaminophen overdose patients experienced vomiting while receiving oral NAC [66]. Administration of NAC through an enteral tube in patients that can protect their airways minimizes the nausea caused by the unpleasant odor (Grade III). If vomiting remains a problem, antiemetics may be helpful (Grade III). Scharman reported in a retrospective review of 78 patients with vomiting due to acute acetaminophen poisoning that the vomiting could not be controlled with antiemetic agents in only three patients who finally were treated with IV NAC [67]. Allergic skin reactions were reported in 13 of 515 acetaminophen overdose patients while receiving oral NAC [66]. Anaphylactoid reactions to oral administration of NAC have not been reported, outside of a single case of angioedema [68]. A serum sickness-like disorder with fever, arthritis, adenopathy, rash, and thrombocytopenia occurred in a young man 3 days after starting oral NAC treatment [69].

Intravenous NAC is associated with more adverse events. Anaphylactoid reactions characterized by sudden onset of respiratory distress with dizziness, rash, nausea, bronchospasm, angioedema, and apnea have been reported with intravenous infusion and are thought to be due to high plasma concentrations resulting from overdose or rapid infusion [58, 70–72]. In two instances, these reactions were associated with hypotension and death [73, 74]. The mechanism of this anaphylactoid reaction is believed to be NAC-induced histamine release, and although the role of histamine in these reactions is unclear, some clinicians advocate administration of H_1 -receptor antagonists [75]. Mild anaphylactoid reactions to NAC can be managed by slowing or discontinuing the infusion (Grade III). In many

patients, if it is determined that intravenous therapy is required to prevent acetaminophen-induced hepatic injury, the infusion may be restarted at a slower rate, or oral therapy may be substituted [76] (Grade III). However, given that this reaction is short-lived, and most often mild, many would recommend administration of H₁-receptor antagonists and continue the infusion at the same rate to avoid lowering NAC concentrations below the efficacy threshold (Grade III).

Following the publication of a randomized controlled trial which evaluated the difference in reactions with different infusion rates, some authors recommend routine administration of the initial infusion over 1 h rather than over 15 min. This likely results in reduction of the peak plasma concentration of NAC and may thereby decrease the risk of anaphylactoid reactions, even though the incidence of drug-related adverse events was not shown to be statistically different [77] (Grade II-2). Moreover, the incidence of anaphylactoid reactions seems to be lower in patients with high acetaminophen concentration after an overdose [78].

Vomiting, flushing, rash, pruritus, chest pain, cough, bronchospasm, headaches, dizziness, and convulsions have also been reported with intravenous NAC [79]. Others reported a decrease in prothrombin time at the beginning of NAC infusion in patients without liver impairment [80]. An increase in the international normalized ratio (INR) attributed to an inhibition of factor VII by NAC has also been reported [81–83].

Adverse effects have been reported with intravenous NAC overdose. One author reported a fivefold NAC overdose resulting in hemolysis and hemolytic uremic syndrome [84]. Others discussed a patient who developed cerebral edema and seizures after receiving 100 mg/kg/h for several hours instead of 100 mg/kg over 16 h [85].

The only absolute contraindication to the use of NAC is a well-documented history of a prior severe allergic reaction. In these cases, the benefits of treatment must be weighed against the potential severity of anaphylaxis. True allergic

reactions to NAC are rare because most individuals do not have prior exposure and are therefore not sensitized. With the use of NAC as a dietary supplement, the number of people with prior exposure and the possibility of sensitization may increase (Grade III).

Treatment and Administration

The traditional US dosing protocol (see below) for oral NAC was based on the amount needed to protect experimental animals from acetaminophen toxicity extrapolated to humans with an added safety factor [86]. At the time when NAC's first use was being studied, it was thought that the drug acted primarily as a glutathione surrogate. From the early animal work, it was known that liver injury occurred after the depletion of hepatic glutathione by 70%. Extrapolating from animals, it was estimated that the typical 70-kg human had approximately 6 mmol of glutathione in the liver. The dose of NAC necessary to compensate for a 70% level of depletion was calculated and multiplied by a threefold safety factor to produce the dose that currently is in use. The duration of treatment was determined by taking the worst-case scenario half-life of 12 h, multiplying it by 5 to account for total disappearance. The FDA requested the inclusion of an additional safety factor of 12 h, resulting in the 72-h treatment protocol. This was the best information available at the time that could be used to develop an acceptable protocol for the FDA. With time and experience, the dose and duration have proved effective [87]. The lowest effective dose of NAC for most acetaminophen overdose situations and the optimal duration of treatment are unknown. It is likely in most cases that far more NAC is being given for longer than actually needed.

In the United States, the traditional, although rarely used, oral dosing schedule for NAC is technically an oral loading dose of 140 mg/kg followed by a 70-mg/kg dose every 4 h for 17 doses [23] (Grade II-2). The solution of NAC

should be diluted to a 5% concentration with juice or a soft drink to attempt to enhance palatability [23, 66] (Grade III). It can also be administered via an enteral tube in patients with a protected airway to avoid the risk of aspiration, if vomiting occurs. If vomiting occurs within 1 h of administration, the vomited dose should be repeated (Grade III). As stated previously, the duration of treatment is probably longer than necessary in the great majority of cases, and shorter protocols are almost always used in patients treated orally. A retrospective study of 305 hospital cases of acetaminophen poisoning reported that, in patients who do not show evidence of hepatotoxicity within 36 h of an acetaminophen overdose, treatment with oral NAC may be stopped when the serum acetaminophen is no longer detectable [88] (Grade III). Although, not formally validated, most medical toxicologists empirically stop NAC treatment, APAP concentrations are less than 10 $\mu\text{g/mL}$ (66 $\mu\text{mol/L}$), which is the detectable threshold in most laboratories. If hepatic transaminases or INR were initially abnormal, therapy is generally continued until these are improving.

Prescott and colleagues' intravenous protocol is preferred in most countries and in the United States since the FDA approval of an intravenous formulation in 2004 [89]. Prescott's protocol is 150 mg/kg given intravenously over 15 min followed by 50 mg/kg over 4 h and then 100 mg/kg over 16 h (Grade II-2). This regimen has been shown to be almost universally effective if started within 10 h of ingestion [89]. The other intravenous protocol uses a 140-mg/kg loading dose followed by 70 mg/kg every 4 h for 48 h [51]. Both oral and intravenous protocols have similar efficacy [87].

The administration time of Prescott protocol's first bolus was changed from 15 to 60 min following a 2005 Australian study examining these two durations, even though the study conclusion states that the adverse event profiles were not statistically different between the two infusion periods [77] (Grade II-2).

In children and adult patients weighing less than 40 kg, the 21-h protocol remains the same but the volume of diluent varies. There are no

official recommendations for patients weighing more than 100 kg. A secondary analysis of a retrospective cohort study looked at dosing of NAC in patients weighing more than 100 kg and found that clinicians often use actual body weight [90]. The severity of obesity could not be evaluated because the body mass index was not reported. It is believed that the volume of the functional liver remains constant even in obese patient and that lean weight may be more appropriate to estimate liver size and NAC requirements.

In a 2012 commentary, Rumack questioned the preferred protocol duration and pointed out that extending the third infusion beyond 16 h when the acetaminophen concentration is still detectable (10 $\mu\text{g/mL}$ or 66 $\mu\text{mol/L}$) or when transaminases are still rising is now considered standard of practice [86] (Grade III). Many speculate that the dose administered should be based on the acetaminophen body burden and the duration of five half-lives for acetaminophen removal (Grade III). This theory has not yet been formally studied, but has been translated in practice in many ways, one of which includes doubling the infusion rate of the third bag in the presence of a very high acetaminophen concentration (Grade III). What is considered a very high concentration seems to vary significantly among experts. A recent international survey showed that one-third of the respondents considered doubling the third infusion if the acetaminophen concentration was greater than 453 $\mu\text{g/mL}$ (3,000 $\mu\text{mol/L}$) [91]. The same survey showed that two-thirds believed that doubling the NAC rate of infusion would be appropriate in patients receiving continuous renal replacement therapy or hemodialysis. The EXTRIP group, in their acetaminophen poisoning publication, made a strong recommendation based on a very low level of evidence that NAC should be continued at an increased rate during extracorporeal treatments due to its significant extraction with hemodialysis [92] (Grade III).

The 21-h Prescott protocol is complicated due to three different infusion rates. A retrospective chart review of 227 patients in a regional poison center showed that one-third of the patients had medication errors [93]. Eighteen percent of the patients had an interruption of the infusion of

more than 1 h. When NAC is interrupted, factors such as the amount of acetaminophen still estimated to be present in the blood and the presence or risk of hepatotoxicity need to be considered to know at what rate to restart the infusion. Although there is no guidance from the manufacturer or published recommendation, it is advised that if more than 2–3 h have elapsed, the entire protocol, including the loading dose, should be restarted. Others recommend restarting at the second infusion. In circumstance where the NAC infusion is stopped for longer than 30 min, advice from the local medical toxicology service or poison center is recommended (Grade III).

The amount of fluid to dilute NAC with cerebral edema accompanying liver failure is debated. It might be safe to prepare more concentrated solution of NAC for the second and third infusion using 100-mL and 250-mL bags instead of 500 mL and 1,000 mL. The final concentration would still be smaller than the first infusion and also smaller than the 40 mg/mL suggested to decrease the risk of hyponatremia in the pediatric population [94]. Even though NAC is hyperosmolar, the osmolality of the more concentrated solution would still be lower than the maximum osmolality recommended for peripheral administration.

The future of acetaminophen overdose treatment may become patient-tailored therapy [95]. The NAC dose could be based on the acetaminophen concentration and time from ingestion considering the difficulty in measuring NAPQI directly [86]. Research is ongoing to identify a more specific marker for evolving toxicity like the 3-*para*-cysteinyl acetaminophen and acetaminophen protein adducts. However, these approaches have not yet been proven to be of added value compared to other markers [96, 97].

Nitrites have been used in a variety of food packaging, manufacturing, and medical settings for more than 150 years. The therapeutic benefit of nitrites was first investigated in the mid-1800s, when nitroglycerin was used as a treatment for angina [1]. Antidotal use of nitrites currently is reserved as a secondary treatment for cyanide poisoning and for consideration in the treatment of severe hydrogen sulfide poisoning. There are no human studies that are available to demonstrate benefits of nitrites in hydrogen sulfide overdoses. Animal studies of nitrites for hydrogen sulfide are equivocal. In the USA, two nitrite agents were packaged together in the cyanide antidote kit (originally manufactured by Eli Lilly and Company); the current cyanide antidote kit contains sodium nitrite (NaNO_2) injection and sodium thiosulfate injection (Nithiodote[®], Hope Pharmaceuticals, Scottsdale, AZ). These agents have been used for the treatment of cyanide toxicity since the 1930s. However, since its approval by the US Food and Drug Administration in 2006, hydroxocobalamin is considered the preferred cyanide antidote in the USA, Europe, and Australia [2].

History

Amyl nitrite was first investigated by Guthrie in 1859 for the treatment of angina [3]. Initial descriptions of the actions of amyl nitrite

B.D. Anderson (✉)
School of Pharmacy, University of Maryland-Baltimore,
Baltimore, MD, USA
e-mail: banderso@rx.umaryland.edu

inhalation included profound vasodilatory effects: “When inhaled in doses of from 5 to 10 drops, nitrite of amyl produces in man violent flushing of the face, associated with a feeling as though the head would burst, and a very excessive action on the heart” [2]. At the time, inhaled amyl nitrite was recommended for a variety of conditions, including angina, asthma, tetanus, seizures, strychnine poisoning, and hysterical convulsions. The earliest described use of amyl nitrite as a potential cyanide antagonist was in 1888 by Pedigo [4].

These findings were followed by Mladoveanu and Gheorhiu [5] in 1929 with sodium nitrite being used to block lethal doses of cyanide in dogs. In 1932, Geiger [6] used methylene blue as a methemoglobin former in experimental cyanide poisoning. In 1933, Mota [7] published the first human case of cyanide poisoning successfully managed with sodium nitrite alone. That same year, Chen and colleagues [8, 9] showed dramatic improvements in survival when nitrites were paired with sodium thiosulfate in a canine model of cyanide poisoning. These studies led to the development of the original cyanide antidote kit, which contained sodium thiosulfate plus amyl and sodium nitrites.

Properties

Amyl Nitrite

The molecular weight of amyl nitrite (Fig. 1) is 110 g/mol. It is a clear, yellow, volatile, flammable liquid with an unpleasant, fruity odor. It is nearly insoluble in water but miscible with alcohol and ether [10].

Sodium Nitrite

Sodium nitrite (NaNO_2) has a molecular weight of 69 g/mol. It exists as white or slightly yellow, hygroscopic granules, rods, or powder with a mild saline taste. In aqueous solution, sodium nitrite has a pH of 9 [11].

Fig. 1 Chemical structure of the two primary constituents of amyl nitrite

Pharmacokinetics

Absorption

Amyl nitrite is absorbed rapidly via inhalation. Its clinical effects may be seen within seconds and typically continue for 5–10 min.

Sodium nitrite is rapidly absorbed following intravenous (IV) administration with rapid onset of vasodilation.

Metabolism

Nitrite is converted almost completely to nitrate within 1 h and is largely excreted in urine; 33% of the dose is excreted as unchanged nitrate. Urinary nitrite and nitrate concentrations in normal healthy volunteers average 0.2 mg/L and 61 mg/L, respectively [12, 13].

In unexposed persons, plasma nitrite and nitrate concentrations average 0.19 mg/L and 1.22 mg/L, respectively [13]. Serum nitrite concentrations have not been assessed during treatment for cyanide poisoning. As nitrites induce methemoglobinemia, measurement of methemoglobin concentration is frequently used as a marker of nitrite activity.

Pharmacodynamics

The original cyanide antidote kit and the mechanism of action of nitrites in cyanide poisoning were originally described by Chen in 1933 [9]. Cyanide blocks the activity of cytochrome

Fig. 2 Schematic diagram of cyanide's distribution and elimination. At physiologic pH, virtually all cyanide is present as hydrogen cyanide (HCN). HCN that has entered plasma after absorption is concentrated within red blood cells, at least in part by binding to the normally small amount of methemoglobin, which contains ferric (Fe^{3+}) iron. HCN also easily diffuses across cell membranes into various organs, where it binds to and inhibits many

enzymes, the most important being cytochrome oxidase. HCN binds to the binuclear center (copper and iron) of cytochrome oxidase to inhibit electron transport through this complex. This produces a decrease in oxygen consumption and, indirectly, a decrease in adenosine triphosphate formation. HCN is detoxified by transsulfuration to thiocyanate (SCN^-), which is excreted in the urine

oxidase, preventing the use of oxygen for cellular respiration (Fig. 2). Nitrites oxidize hemoglobin to form methemoglobin. Because of its high affinity for methemoglobin, cyanide preferentially binds to methemoglobin, forming cyanmethemoglobin (Fig. 3). Further elimination of cyanide occurs through the conversion of cyanide to thiocyanate (SCN^-) via rhodanese. Sodium thiosulfate serves as a substrate for rhodanese, enhancing cyanide clearance.

Despite these findings and the demonstrated clinical benefit of nitrite administration in cases of cyanide poisoning, other pathways for cyanide detoxification have been investigated [14, 15]. In clinical settings, methemoglobin formation lags behind the clinical response to nitrite treatment [15–17]. In experimental animal studies of cyanide exposure in which methemoglobin formation is blocked by administration of methylene blue, the antidotal response to nitrite administration is retained [18].

These observations, plus the enhanced understanding of mitochondrial nitric oxide synthase, led to the discovery of the role of nitric oxide (NO) in electron transport and its importance in the treatment of cyanide poisoning. Nitric oxide alters intracellular binding of cyanide to cytochrome c oxidase in mitochondria, actually displacing cyanide from its binding site [19, 20]. Pearce et al. found that nitric oxide not only functions as a competitive inhibitor of cytochrome c oxidase but is also a substrate which is metabolically converted to nitrite. The displaced cyanide may then be directly converted to thiocyanate or bound to methemoglobin.

Similar to many poisonings, cyanide-exposed patients experience a broad continuum of effects. Wurzburg [21] described a series of patients with acute occupational cyanide exposure who were managed successfully with amyl nitrite and supplemental oxygen alone. In this setting, some workers underwent treatment and were able to return to work and complete their shifts. Other cases describe the

Fig. 3 Antidotal strategies in the treatment of cyanide toxicity with nitrites and thiosulfate. Hydrogen cyanide (HCN) binds to tissue cytochrome oxidase to inhibit oxidative phosphorylation. Nitrite (sodium nitrite or amyl nitrite) converts some ferrous hemoglobin (Fe²⁺) to methemoglobin (Fe³⁺), creating a large circulating sink of ferric iron. HCN quickly

dissociates from cytochrome oxidase and moves from tissue to bind to methemoglobin, forming cyanmethemoglobin and reversing inhibition of cytochrome oxidase. As cyanmethemoglobin is reduced back to Fe²⁺, HCN is released. Sodium thiosulfate markedly enhances transsulfuration of HCN to thiocyanate (SCN⁻)

survival of cyanide-poisoned patients managed simply with aggressive supportive therapy [22, 23]. Survival of patients with even higher whole-blood cyanide concentrations has been reported following treatment with the combination of antidotal and supportive therapies [15, 16, 24].

Overaggressive nitrite use is associated with hypotension, reflex tachycardia, syncope, and cyanosis. One death has been reported secondary to excessive nitrite use [25]. Nitrites are considered secondary treatments for cyanide poisoning and should not be given indiscriminately.

Special Populations

Amyl nitrite and sodium nitrite are listed as US Food and Drug Administration pregnancy risk category C (evidence of teratogenicity in animals but not in

humans) [26]. Patients who are anemic should have the nitrite dose adjusted based on blood hemoglobin concentration (Table 1) [25]. The formation of any amount of methemoglobin in these patients causes a proportionally higher percentage of methemoglobin. Concerns over the administration of nitrites to victims of smoke inhalation exist as nitrite-induced methemoglobin formation may further limit the oxygen-carrying capacity of blood in the presence of carbon monoxide [27]. However, this limitation needs to be understood and managed in the clinical setting of severe and potentially fatal poisoning [28].

Contraindications

Cyanide poisoning is potentially life-threatening. Although some conditions (e.g., severe anemia, methemoglobinemia) may have been at

Table 1 Adjustment of sodium nitrite dose with hemoglobin concentration

Hemoglobin (G/DL)	Initial dose of sodium nitrite (Mg/Kg)

12	10.0
13	10.8
14	11.6

Adapted from Berlin [25]

heightened risk for nitrite toxicity, there are no absolute contraindications to nitrite therapy in the management of cyanide poisoning.

Precautions

Patients with Profound Hypotension

Despite the ability of nitrite therapy to produce vasodilation with resultant hypotension, their use in cyanide poisoning is not contraindicated. The rationale for this is that because cyanide poisoning causes life-threatening hemodynamic compromise, therapy – including with nitrites – is expected to improve overall hemodynamic status. However, treatment with hydroxocobalamin is preferred over nitrite treatment for cyanide overdose in part because of its safety and tolerability.

Patients Taking Phosphodiesterase Inhibitors

There is no specific clinical experience with patients using phosphodiesterase inhibitors being treated with amyl nitrite or sodium nitrite for cyanide poisoning. However, a pronounced hypotensive effect is expected based on the interaction between phosphodiesterase inhibitors and other nitrites [11].

Other Patients

Amyl nitrite is extremely flammable. It should be kept away from any source of open flame or spark.

Adverse Effects

Signs and symptoms of hypotension (dizziness, fainting, mental status changes) are common with cyanide exposures and with nitrite administration. Headache is a commonly encountered side effect, especially following amyl nitrite use. This effect generally is short-lived.

Administration

Amyl Nitrite

Nitrites are now considered part of a secondary treatment for cyanide overdose. The primary treatment is hydroxocobalamin. However, in the setting where hydroxocobalamin is not available but nitrites are, amyl nitrite pearls may be broken in gauze, cloth, or a sponge and then held close to the nose and mouth of a spontaneously breathing patient. In patients requiring assisted ventilation, the broken pearls may be placed into the lip of the face mask, inside the resuscitation bag, or in a port access of an endotracheal tube. Directions for administration of amyl nitrite from the previous version of the cyanide antidote kit were glass pearls should be crushed in gauze and inhaled for 30 s out of each minute. The pearls could be replaced with a fresh one every 2–4 min, and the use of amyl nitrite should be considered, at best, a temporary measure until sodium nitrite can be administered [29].

Sodium Nitrite

If the determination is made to use nitrite therapy after IV access is established, sodium nitrite may be considered a part of the secondary antidote for cyanide poisoning (along with sodium thiosulfate) when hydroxocobalamin is unavailable (level III recommendation). It is possible in patients with a positive clinical response to amyl nitrite and supportive care that sodium nitrite therapy may not be needed. In patients with

significant cyanide poisoning and when hydroxocobalamin is unavailable, sodium nitrite and thiosulfate should be administered as soon as possible (level III recommendation).

The usual adult intravenous dose of sodium nitrite is 300 mg (one 10-mL vial of a 3% solution); the pediatric dose is 0.12–0.33 mL/kg to a maximum of 300 mg (10 mL) (level III recommendation) [22]. The dose can be given intravenously over at least 5 min or diluted in 50–100 mL of intravenous fluid and infused slowly (level III recommendation). Blood pressure monitoring is essential during nitrite administration [25].

Early animal studies showed the superiority of the combination of nitrite and thiosulfate over either agent alone in the treatment of cyanide poisoning [8, 9]. The use of sodium nitrite plus sodium thiosulfate was shown to be protective to 18 times the median lethal dose of cyanide in dogs. If sodium nitrite is given for cyanide poisoning, it should be followed by an appropriate dose of sodium thiosulfate (level III recommendation).

Octreotide (Sandostatin) is a synthetic analogue of somatostatin that has similar, if not identical, pharmacologic activity to this endogenous hormone but is longer acting and more potent [1–11]. Somatostatin was first isolated from the hypothalamus and characterized as an inhibitor of pituitary growth hormone secretion in 1973 [12]. It is synthesized and widely distributed throughout the body (particularly in neurons, pancreas, and gastrointestinal tract but also in immune and inflammatory cells), modulates neurotransmission (primarily in the central nervous system), and has generalized inhibitory effects on paracrine function. With respect to the last-mentioned, somatostatin inhibits the release of the following:

Thyrotropin
Prolactin
Gastrin
Motilin
Vasoactive intestinal peptide
Pancreatic polypeptide
Glicentin
Glucagon
Insulin
Insulin-like growth factors (somatomedins)
Parathyroid hormone
Luteinizing hormone
Calcitonin
Renin
Adrenocorticotrophic hormone
Growth hormone

This is an update of the chapter written by Christopher H. Linden for the first edition of this text.

Somatostatin is involved in the regulation of many physiologic processes and also inhibits exocrine secretions from the pancreas, gut, gallbladder, and salivary glands. It consists of two main peptides, SST-14 and SST-28, which bind to and activate five related G-protein coupled receptors [1–5]. Octreotide, lanreotide, and pasireotide are the only three somatostatin analogs currently in widespread clinical use and approved for use in the USA. Octreotide and lanreotide are cyclic octapeptides, while pasireotide is a cyclohexapeptide. They display the greatest affinity for somatostatin type 2 and type 5 receptors found in the pituitary gland and the pancreas [6–12].

Indications for the use of octreotide currently approved by the US Food and Drug Administration are limited to the treatment of acromegaly, carcinoid tumors, and vasoactive intestinal peptide tumors [11]. Clinical experience also supports its use in the treatment of nonsecretory, corticotropin-secreting, and thyrotropin-secreting pituitary adenomas; pancreatic islet cell tumors; congenital and acquired hyperinsulinism; nesidioblastosis; acute pancreatitis; pancreatic fistulas and pseudocysts; bleeding from esophageal varices and peptic ulcers; and diarrhea associated with ileostomies, short bowel syndrome, intestinal graft-versus-host disease, radiation colitis, intestinal fistulas, and acquired immunodeficiency syndrome [6–10, 13, 14]. Its effects on other endocrine disorders, nonendocrine tumors, hematologic function, immunologic function, neurologic function, vascular disease, and a host of other processes, including aging, are under investigation. Lanreotide is a longer-acting depot preparation used for acromegaly and gastroenteropancreatic neuroendocrine tumors. Pasireotide is used to treat acromegaly and Cushing's syndrome.

The ability of octreotide to inhibit the secretion of insulin, glucagon, and other insulin counterregulatory hormones makes it a rational choice for the treatment of poisoning due to sulfonylureas and other drugs causing hyperinsulinemia (see ► Chap. 70, "Antidiabetic Agents"). With proven efficacy, low cost, ease of administration, and a highly favorable safety profile, it has virtually all the properties characterizing an ideal antidote.

Although much more is known about the pharmacology of octreotide (and somatostatin), the remainder of this chapter focuses only on the actions relevant to the understanding and treatment of drug-induced hyperinsulinemic hypoglycemia.

Pharmacodynamics

Physiologically, somatostatin acts as a gastrointestinal and pancreatic counter-regulatory hormone [1, 3, 15]. It is secreted from pancreatic islets of Langerhans delta cells in response to increases in blood glucose, amino acids, fatty acids, and gastrointestinal hormones that occur after the ingestion of food. Systemic effects include decreased gastrointestinal and gallbladder motility and secretory activity with consequent slowing of the digestion and absorption of food. Locally, somatostatin inhibits the pancreatic secretion of insulin from islet beta cells and of glucagon from islet alpha and intestinal alpha-like or L cells, decreasing the uptake and use of absorbed nutrients. Although pancreatic alpha cells are about 50 times more sensitive to somatostatin than beta cells, their effect on insulin secretion is more prolonged than that on glucagon secretion. Teleologically, by preventing the rapid assimilation and consequent exhaustion of ingested food, somatostatin lessens inequalities between the intermittent supply and continuous demand for nutrients, increasing the overall efficiency of food processing.

Sulfonylurea drugs counteract hyperglycemia by enhancing the release of insulin from pancreatic islet beta cells in response to glucose, the principal stimulus and an essential permissive factor for insulin secretion [3, 16, 17]. Their mechanism of action is similar to that of high plasma glucose concentrations: inhibition of the pancreatic islet beta cell membrane adenosine triphosphate (ATP)-sensitive potassium (K^+) channels leading to membrane depolarization with consequent calcium (Ca^{2+}) influx through voltage-sensitive Ca^{2+} channels, mobilization of Ca^{2+} from the endoplasmic reticulum, increased intracellular Ca^{2+} , and insulin secretion.

Fig. 1 Schematic diagram of a pancreatic beta cell showing the regulation of insulin secretion. Glucose is transported into the beta cell by a glucose-transporter protein (GLUT-2). The enzyme glucokinase (GK) initiates glycolysis by catalyzing the transfer of phosphate from adenosine triphosphate (ATP) to glucose, resulting in the formation of glucose-6-phosphate (G-6-P). ATP generated by subsequent steps in the glycolytic pathway and by the Krebs (citric or tricarboxylic acid) cycle leads to closure of ATP-sensitive potassium channels (K^+_{ATP}) and membrane depolarization. Membrane depolarization results in opening of voltage-dependent calcium channels (Ca^{2+}_{VD}), influx of extracellular calcium, and subsequent release of calcium from intracellular (endoplasmic reticulum) stores. Increased intracellular calcium promotes the exocytosis

of insulin granules (Golgi vesicles) with release of insulin into extracellular fluid and the systemic circulation. Although the phosphorylation of glucose is a rate-limiting step, beta cell GK has a high Michaelis constant (K_M , the substrate concentration at which the reaction rate is half of the maximal value) for glucose. Glucose metabolism and ATP production, potassium and calcium channel activity, intracellular calcium concentration, and insulin release are controlled primarily by the intracellular glucose concentration. Sulfonylureas (SU) inhibit potassium efflux by binding to specific receptors (SUR) associated with K^+_{ATP} channels and enhance the release of insulin. Somatostatin (SST) and its analogues, such as octreotide, inhibit calcium influx by binding to receptors (SSTR) associated with Ca^{2+}_{VD} channels, inhibiting the release of insulin

Sulfonylureas bind to specific receptors associated with K^+ channels on the beta cell membrane, whereas glucose generates ATP through its oxidative metabolism within beta cells. Intracellular Ca^{2+} is the ultimate insulin secretagogue, with increases in intracellular calcium promoting the synthesis and release of insulin (Fig. 1).

The action of octreotide (and of somatostatin and other analogues) on beta cell Ca^{2+} disposition is diametrically opposite to that of the sulfonylureas, and the mechanism is slightly different [3, 18, 19]. Octreotide binds to specific somatostatin membrane receptors (SST receptors or SSTRs) associated with Ca^{2+} channels, resulting in decreased calcium conductance, decreased intracellular Ca^{2+} , and inhibition of insulin secretion. Opening of potassium channels with subsequent

membrane hyperpolarization also may be involved. Somatostatin receptors are coupled to G proteins. To date, five SSTR subtypes have been identified. Receptor affinity and selectivity differ from one somatostatin analogue to another. Subtypes 2 and 5 mediate insulin secretion. Octreotide's action does not seem to be mediated by increased potassium efflux through K^+ channels [20]. Suppression of insulin secretion by octreotide has been documented in experimental [21–24] and human sulfonylurea poisoning [25, 26] (see Fig. 1).

The antidotal effects of octreotide in sulfonylurea poisoning also may be due to its antagonism of glucagon and possibly other counterregulatory hormones. Octreotide not only inhibits the secretion of glucagon in response to hypoglycemia but

also inhibits the actions of glucagon [1, 3]. Glucagon activates adenylyl cyclase, which catalyzes the synthesis of cyclic adenosine monophosphate (AMP), whereas octreotide inhibits this enzyme. In the absence of octreotide, this action of glucagon increases cyclic AMP levels, and this stimulates glycogen phosphorylase (the rate-limiting enzyme in glycogenolysis), inhibits glycogen synthase, and increases intracellular Ca^{2+} , effects that may lead to hyperglycemia, rebound hyperinsulinemia, and recurrent hypoglycemia after glucose administration (see Fig. 1 and see ► Chap. 70, “Antidiabetic Agents”). As with insulin, SSTR subtypes 2 and 5 mediate glucagon secretion [18, 19]. Octreotide has been shown to decrease epinephrine, norepinephrine, and glucagon levels in experimental models of glipizide overdose [21].

Octreotide also is likely to be effective in treating hyperinsulinemic hypoglycemia due to other drugs, including insulin itself (see ► Chap. 70, “Antidiabetic Agents”). One report described improvement in glucose concentrations after octreotide was administered to a 56-year-old male who overdosed on insulin glargine [27]. The meglitinides (repaglinide and nateglinide) act similarly to sulfonylureas to increase insulin secretion by blocking ATP-dependent potassium channels. This leads to depolarization of the membrane and facilitates calcium entry through calcium channels, thereby stimulating insulin release from the pancreatic beta cells. At least one report described successful treatment of repaglinide-induced hypoglycemia with octreotide [28]. Its use has also been reported in a case of quinine-induced hypoglycemia [29]. Octreotide is relatively inexpensive, costing less than \$10 US for a 100- μg dose.

Pharmacokinetics

Octreotide is well-absorbed after subcutaneous administration, with peak plasma concentrations averaging 5.2 ng/mL 0.4 h after a 100- μg dose in healthy volunteers [11]. It is about 65% bound to plasma lipoproteins, has a small volume of distribution (approximately 0.2 L/kg), and a half-life of

about 1.7 h, which is much longer than that of somatostatin (1–3 min). About one third of the dose is excreted unchanged in the urine, and the half-life is doubled in renal dialysis patients and the elderly. The metabolic fate of the remaining fraction has not been determined.

Octreotide is also absorbed after oral administration, though bioavailability is low. A 2-mg oral dose results in peak plasma drug levels similar to a 50- μg subcutaneous dose, with the time to peak level delayed about 1.5 h.

Contraindications and Adverse Effects

Except for hypersensitivity, there are no contraindications to octreotide use [1, 3, 5–11]. Overall, octreotide is well tolerated. As with most subcutaneously administered medications, burning pain at the injection site can occur. In the three largest studies and case series evaluating octreotide for sulfonylurea poisoning in adults, no adverse effects were reported among almost 40 patients [30–32]. Similarly, a larger retrospective study in pediatric patients reported no adverse effects in 121 patients [33]. There are a few scattered reports of adverse effects temporally related to octreotide administration for sulfonylurea poisoning, but a cause-and-effect association is unclear. A pediatric patient developed hypertension and apnea 30 min after administration of octreotide; the dose was not reported [34]. Hyperkalemia and worsening heart failure have each been reported once, both in adult patients [35, 36]. When used for congenital diseases such as acromegaly and hyperinsulinism, octreotide has been associated with cases of drug-induced hepatitis [37–40]. However, there may have been other contributing factors and the hepatitis occurred after prolonged use in each case. Hepatitis has not been reported with the short-term therapeutic use of octreotide for sulfonylurea overdose.

Octreotide has been used in all age groups, including neonates and pregnant women. Although no adverse effects on fertility or fetal development have been noted in experimental animals, because octreotide has not been studied extensively in pregnant women, it has a Food and Drug

Administration category B use-in-pregnancy rating (no evidence of risk in humans; the chance of fetal harm is remote but remains a possibility).

Treatment

There have been numerous case reports, case series, retrospective studies, and even randomized controlled trials examining octreotide for sulfonylurea poisoning. Both pediatric and adult populations have been studied. One of the earliest studies demonstrated that a continuous octreotide infusion (30 ng/kg/min or 126 µg/h for a 70-kg person) was effective in lessening the severity of hypoglycemia in nondiabetic human volunteers ($n = 8$) who ingested a large dose of glipizide (1.45 mg/kg) [21]. This therapy reduced the need for exogenous glucose in all subjects and entirely eliminated it in half. It was also found that without octreotide, some patients experienced recurrent hypoglycemia up to 30 h following glipizide ingestion.

Pediatric Patients

There are at least 10 published reports of octreotide use in pediatric patients [33, 34, 43–50]. Fifteen children are discussed in nine small studies [34, 43–50]. Ages ranged from 1 to 17 years with most under age 6 years. Fourteen of the 15 children ingested second-generation sulfonylureas (eight glipizide and six glyburide or glibenclamide); the drug was not reported in the remaining case. Octreotide was generally administered after intravenous (IV) 10–50% dextrose boluses and infusions failed to correct hypoglycemia or maintain euglycemia. The dose range of octreotide was 0.51–2.5 µg/kg IV or SC; most patients received octreotide 1–1.5 µg/kg IV. Octreotide resulted in correction of the serum glucose concentration in all 15 patients and recurrent hypoglycemia was observed in eight. Seven patients received additional octreotide doses as IV boluses or infusion. Time to recurrent hypoglycemia after octreotide administration ranged from 6 to 17 h.

One group retrospectively examined 9 years of the American Association of Poison Control Centers' National Poison Data System to evaluate octreotide as an antidote for sulfonylurea overdose in children younger than 6 years of age [33]. One hundred twenty one cases were identified in which a child ingested a sulfonylurea and experienced at least one episode of hypoglycemia (median age 22 months). Prior to octreotide administration, the median glucose concentration was 44 mg/dL (range 2–62 mg/dL). Glipizide was the most frequently ingested sulfonylurea accounting for 70% of cases. Though octreotide doses were not recorded, the number of hypoglycemic episodes before octreotide (median, 2) was significantly higher than after octreotide (median, 0; $P < 0.0001$). After octreotide, 99 of 121 had no further hypoglycemic episodes. Twenty-two children experienced a hypoglycemic episode after the first dose of octreotide, occurring at a median time of 5 h (range, 1–25 h) after administration. Further details about these cases were not reported.

Adult Patients

At least 16 published reports describe octreotide use for sulfonylurea poisoning in adults [25, 30–32, 35, 36, 41, 42, 51–58]. Thirteen case reports (16 patients) described exposures to first and second generation sulfonylureas, with 10 identified as glyburide/glibenclamide or glipizide [25, 35, 36, 41, 42, 51–58]. The most common dose of octreotide was 50 µg subcutaneously, followed by 50 µg subcutaneously every 6–12 h for 2–3 doses. A 100 µg subcutaneous dose was also used in a few cases, followed by 50–100 µg subsequent doses. Two patients were treated with octreotide by continuous IV infusion (30 ng/kg/min for 13 h, and 50 µg/h). Five patients developed recurrent hypoglycemia 2–9 h after octreotide was administered. Six patients had serum insulin or C-peptide levels measured during hypoglycemia; all were elevated. Three of the six had repeat levels drawn after octreotide administration; all had decreased.

Six adult patients were reported in a case series, all of which experienced hypoglycemia after therapeutic doses of sulfonylureas (4 glimepiride, 1 glyburide, and 1 glipizide) [32]. Intermittent IV administration of 50% dextrose did not result in a sustained and adequate blood glucose response. The patients were treated with octreotide 50 µg subcutaneously every 8 h, receiving 2–4 doses. Half experienced recurrent hypoglycemia after initial octreotide administration. Three patients had serum insulin and C-peptide levels measured during hypoglycemia; all were elevated and decreased after octreotide. Nine adult patients were retrospectively reviewed after ingestion of a sulfonylurea (6 glyburide and 3 glipizide) [30]. The initial octreotide dose was 40–100 µg subcutaneously, followed by 40–100 µg subcutaneously every 6–12 h, 2–3 doses in six patients and 125 µg/h IV for 9 h in one patient. There were 3.2 hypoglycemic events per patient recorded before octreotide compared to 0.2 per patient after octreotide ($p = 0.008$). There were 72.5 g of 50% dextrose administered before octreotide compared to 5 g after octreotide ($p = 0.004$). Two patients had recurrent hypoglycemia, one 14 h after octreotide and the other 36 h after octreotide. In the first patient, hypoglycemia occurred more than 30 h after the ingestion of glyburide. The second patient experienced recurrent hypoglycemia 40 h after ingestion of extended-release glipizide. Both were beyond the duration of effect of octreotide.

One randomized, double-blind, placebo controlled trial exists evaluating the efficacy of octreotide in sulfonylurea poisoning [31]. In addition to standard dextrose therapy, 22 patients received octreotide 75 µg subcutaneously after sulfonylurea-induced hypoglycemia. Eighteen patients served as controls and received placebo in addition to standard dextrose therapy. The mean glucose values for octreotide patients compared with placebo were consistently higher during the first 8 h but showed no difference in subsequent hours. The mean glucose difference in the octreotide group versus placebo was 56 mg/dL in hours 1–3 after administration and 127 mg/dL in hours 4–8. Ten octreotide-treated patients experienced recurrent hypoglycemia

compared with six patients in the control group. Only one dose of octreotide was administered. All patients were admitted to the hospital and monitored for recurrent hypoglycemia for at least 24 h.

Indications for octreotide treatment are not well defined. Although it is generally agreed that octreotide is indicated for recurrent hypoglycemia due to sulfonylurea poisoning, whether it should be given after the first episode of hypoglycemia is unclear. Doing so is reasonable in patients who are likely to develop further episodes (e.g., patients with large or intentional overdoses or children with an unsupervised ingestion of an unknown amount), but it may prolong unnecessarily the period of observation for patients who are not (e.g., patients with therapeutic misadventures). As always, the reliability of the history must be assessed when making such decisions. Given that the overdose history is often inaccurate, incomplete, or unobtainable, we prefer to reserve treatment for patients with a documented second episode of hypoglycemia (Grade III recommendation). Treatment recommendations for these patients are discussed in detail in ► [Chap. 70, “Antidiabetic Agents.”](#)

Administration

Based on clinical experience and the available data, a subcutaneous dose of 1–2 µg/kg (50–100 µg in adults) every 6–8 h can be expected to be effective for the treatment of sulfonylurea-induced hypoglycemia (Grade II-2 recommendation). A continuous IV infusion of the same dose on an hourly basis also is likely to be effective. IV administration is more expensive and more difficult to prepare and administer (and more susceptible to dosing errors). Because there is no evidence that this route and method of dosing are superior or necessary, we recommend intermittent subcutaneous dosing as the preferred treatment regimen. For adult patients, we recommend 100 µg subcutaneously every 6 h (GRADE I recommendation). For pediatric patients, we recommend 1.5 µg/kg subcutaneously every 6 h (Level of Evidence II-3) (Table 1).

Table 1 Octreotide dose recommendations with associated GRADE ratings

Population	Dose	Supporting studies	GRADE rating
Pediatric	1–1.5 mcg/kg subcut	Case reports, case series, and one large retrospective review of national poison center data [33, 34, 43–50]	II-3
Adult	50–100 mcg subcut	13 case reports, 2 case series, and one randomized, placebo, controlled trial [25, 30–32, 35, 36, 41, 42, 51–58]	I

Octreotide is administered parenterally for the treatment of hyperinsulinemic hypoglycemia due to drug overdose. Solutions containing 50 µg/mL, 100 µg/mL, 200 µg/mL, 500 µg/mL, or 1000 µg/mL are available for subcutaneous injection or intravenous infusion. Long-acting, sustained-release preparations containing 10 mg/2 mL, 20 mg/2 mL, or 30 mg/2 mL for intramuscular (intragluteal) injection at monthly intervals (e.g., Sandostatin LAR Depot) are used for the treatment of chronic conditions. No oral formulations of octreotide are commercially available. Similar doses to the above are likely effective for the treatment of other drug-induced states of hyperinsulinism (see ► [Chap. 70, “Antidiabetic Agents”](#)), but there is little experience with its use in this setting.

Despite the long history of opioid use, opioid receptor antagonists were not developed until the twentieth century. The impetus for their development was, at least in part, the increasing incidence of abuse and overdose, coinciding with the understanding that minor structural alterations to certain opioid receptor agonists impart receptor antagonist activity. In the 1940s, *N*-allylnormorphine (nalorphine) was widely used to reverse the adverse effects of opioid receptor agonists, but its mixed receptor agonist-antagonist profile was not defined until 1954 [1]. Further refinements in opioid structure-activity relationships led to the development of naloxone and naltrexone (Fig. 1), the opioid receptor antagonists currently in routine clinical use. Oxymorphone is an opioid receptor agonist with structural similarity to morphine; replacement of the N-17 methyl group on oxymorphone with a larger functional group results in the formation of naloxone and naltrexone [2]. Nalmefene, an opioid receptor antagonist that was discontinued from the US market in 2008, is a 6-methylene derivative of naltrexone.

Pharmacodynamics

Opioid receptor antagonists are structural analogues of opioid receptor agonists and bind effectively at the μ , κ , and δ receptors. These agents exert receptor antagonist activity predominantly at the μ receptor; higher doses are required

Fig. 1 Chemical structures of morphine, nalmefene, naloxone, and naltrexone

to affect the κ and δ receptors. As competitive receptor antagonists, they have no significant effect in the absence of opioid receptor agonists, in opioid naïve, or in non-opioid-dependent patients.

With adequate dosing, opioid receptor antagonists reverse the pharmacologic effects of both endogenous and exogenous opioid receptor agonists at the μ , κ , and δ receptors, as well as prevent opioid agonism if given as a pretreatment. Reversal of opioid agonism corrects most signs of opioid poisoning including: respiratory and CNS depression, analgesia, miosis, inhibition of baroreceptors, vasodilation, and gastrointestinal immobility. Opioid receptor antagonists do not reverse effects that are not mediated through opioid receptor interactions, including opioid-associated histamine release (e.g., morphine and codeine) [3, 4] or the sodium channel receptor antagonist effects of propoxyphene.

The goal of opioid receptor antagonist administration is alleviation of respiratory depression and avoidance of withdrawal precipitation. Rarely it is necessary to administer higher doses (≥ 0.04 mg) of naloxone *initially* because the primary desired effect of naloxone, the reversal of respiratory depression, may be temporized by exogenous ventilation using a bag-valve-mask apparatus. Experimental studies demonstrate that catecholamine surge associated with naloxone administration in hypercapnic animals may be ameliorated by establishment of normocapnia or hypocapnia prior to its administration [5]. The use

of careful naloxone titration to allow slow reversal and spontaneous normalization of hypercapnia may prevent the effect of precipitation of opioid withdrawal yet allow a larger dose ultimately to be administered in the rare instances in which it is required (evidence level II-3) [5]. The most consequential effects of opioid receptor antagonists are at the μ receptor subtype, where they may precipitate the opioid withdrawal syndrome in opioid-dependent patients, characterized by yawning, rhinorrhea, lacrimation, nausea, vomiting, diaphoresis, piloerection, mydriasis, abdominal cramping, diarrhea, and insomnia. Abstinence-related opioid withdrawal is not generally considered life threatening. However, rapid opioid withdrawal, often iatrogenic or precipitated, carries significant morbidity and mortality as profound catecholamine surge can lead to cardiac dysrhythmias and acute lung injury [6]. In addition, precipitating withdrawal-associated emesis in a patient whose mental status is altered concomitantly by another substance (e.g., ethanol) or another condition (e.g., head injury) may lead to catastrophic effects. Specifically, pulmonary aspiration and its sequelae may occur owing to the inability to clear or protect the airway. To that end, the lowest dose necessary to reverse the patient's respiratory depression should be administered initially (e.g., 0.04 or 0.05 mg, depending on the starting concentration of the naloxone preparation) and titrated upward as indicated to 0.4 mg, 2 mg, and possibly up to 10 mg until desired clinical effect is achieved (evidence

level II-3) [7, 8]. However, if no effect is achieved following administration of a total of 2 mg within minutes, the respiratory depression is unlikely to be caused by an opioid receptor agonist. Exceptions to this include toxicity from certain fentanyl derivatives, including acetylfentanyl, α -methylfentanyl (“China White”), and 3-methylfentanyl (“Tango and Cash”), which have increased potency and may require naloxone doses of 2–10 mg to achieve reversal [9, 10].

Certain opioids, primarily buprenorphine, will respond to naloxone less predictably and in a nonlinear fashion compared to other opioid receptor agonists [11, 12]. Studies in healthy human volunteers showed the failure of reversal of buprenorphine-induced respiratory depression with 0.8 mg intravenous naloxone [11]. Reversal of buprenorphine toxicity occurs along a bell-shaped dose–response curve, with doses of 2–4 mg intravenous naloxone being effective. Doses exceeding 5 mg may have decreased reversal potential and may paradoxically increase respiratory depression [11]. Reversal of buprenorphine toxicity with naloxone should be undertaken in a similar manner described above, but with the starting dose of naloxone being slightly higher. For example, initial intravenous naloxone dosing should be 1–2 mg with titration of dosing to reversal of respiratory depression, not to exceed 5 mg in an adult (evidence level II-3) [11].

Pharmacokinetics

Although opioid receptor antagonists are remarkably similar in clinical effects, they differ markedly in their pharmacokinetic profiles. The duration of action of naltrexone (approximately 24 h) is substantially longer than that of naloxone (20–90 min). The practical implication of their pharmacokinetic differences is that opioid effect may recur, particularly if a short-acting opioid receptor antagonist (e.g., naloxone) is administered to a patient exposed to a long-acting receptor agonist (e.g., methadone). For this reason, continuous cardiorespiratory monitoring, including end-tidal capnography (EtCO₂), for recrudescence is required following naloxone

administration. Use of continuous EtCO₂ monitoring may provide the earliest indicator of ventilatory compromise, including rising EtCO₂ levels or loss of waveform, prior to changes in oxygen saturation (SpO₂) [13]. This is particularly important for patients receiving exogenous oxygen. Recurrent sedation and respiratory depression should be treated with an additional naloxone bolus, followed by continuous infusion if additional naloxone dosing is expected. Continuous infusion dosing should be started at two-thirds the dose at which reversal was achieved, administered hourly (evidence level II-3) [14]. Patients receiving continuous naloxone infusions should be monitored closely because of the possible increase in opioid absorption associated with normalization of intestinal mobility, resulting in increased naloxone requirements. Although an agent with a longer duration of action is preferable to promote abstinence and prevent resedation, the risk of inadvertent withdrawal precipitation in an opioid-dependent patient favors initial titration with a short-acting agent.

Contraindications

Opioid receptor antagonists should not be used in certain populations, specifically opioid-dependent neonates, and cautiously used in patients using cocaine (or another stimulant) in combination with opioids, colloquially known as a *speedball*. Naloxone at doses of 0.04 mg titrated to resolution of respiratory depression, as described above, may be administered. Excessive or rapid reversal of a patient with a heroin-cocaine overdose with naloxone may result in the unopposed effects of cocaine and lead to cardiac dysrhythmias or seizures [15]. Opioid-dependent neonates who develop withdrawal may develop life-threatening seizures (see ► Chap. 27, “Withdrawal Syndromes”).

Treatment

In the event that naloxone is administered in excess to a patient presenting with an opioid overdose, the treatment recommended during the

Pharmacokinetics of Opioid Receptor Antagonists

Drug	Route	Dose	Elimination half-life	Duration of effect
Naloxone ^a	IM, IV, ET, SC, IN, IO, PO	Neonate, 0.01 mg/kg	60–90 min	20–90 min
		Adult with opioid dependence, start 0.04 mg and titrate as necessary to avoid withdrawal symptoms and to preserve ventilation	—	—
		Adult without opioid dependence, start at 0.4 mg	—	—
		Continuous infusion, two-thirds of reversal dose, given hourly		
Naltrexone ^b	PO	PO not well absorbed and only used for local GI effects		
		50 mg PO daily	10 h	24 h

ET endotracheal, IM intramuscular, IV intravenous, PO oral, SC subcutaneous, IN inhalational, IO intraosseous

^bFrom Nelson and Howland [25]

period of mild-to-moderate withdrawal is supportive, including reassurance that the withdrawal syndrome is not usually life threatening and will wane rapidly. Symptomatic care, such as antiemetic therapy for severe nausea and vomiting, should be provided. Care should be taken to avoid antiemetic drugs with sedating properties, such as antihistamines or promethazine. We do not recommend treating iatrogenically induced withdrawal syndrome from naloxone with an opioid receptor agonist because it is difficult to titrate an individual’s opioid needs, and naloxone’s short effects wane rapidly without any intervention (evidence level III). However, opioid withdrawal precipitated by naltrexone may last for hours, and attempts to overcome the competitive antagonism with the use of a high-potency, short-acting opioid receptor agonist, such as fentanyl, in titrated doses with continuous monitoring are often successful. Alternatively, in this situation, symptomatic care may suffice, often with the addition of clonidine, a sympatholytic with opio-mimetic effects (evidence level II-3) [16].

Administration

Naloxone must be given by a parenteral route owing to its extensive first-pass hepatic elimination. Naltrexone may be administered orally and typically is used for detoxification and

maintenance of opioid abstinence secondary to its long duration of action.

Although opioid receptor antagonist administration is predominantly done by trained health-care providers, its administration by laypersons is becoming increasingly advocated by proponents of harm reduction and community-based opioid overdose death prevention programs [17]. Providing overdose education and naloxone to opioid users and persons who may be present during or proximate to an opioid overdose (e.g., family, friends, homeless shelter workers, substance abuse treatment program staff) may help to decrease opioid overdose morbidity and mortality. Layperson naloxone administration may be intramuscular or intranasal, based largely on the jurisdictional regulations and availability. Though potentially beneficial in opioid intoxication, reversal following naloxone administration may lead to opioid withdrawal (evidence level II-1) [18].

Other Uses of Opioid Receptor Antagonists

Opioid-induced constipation is a common side effect of opioid receptor agonists due to reduced gastrointestinal motility. Certain opioid receptor antagonists, including methylnaltrexone,

alvimopan, and naloxegol, may be used specifically for reversing opioid-induced bowel dysmotility (evidence level I). These agents do not cross the blood–brain barrier and will antagonize peripheral effects, both desired and not, without reversing desired central effects (e.g., analgesia) [19]. Low-dose oral naloxone may also be used for this indication, because it has poor oral bioavailability [20].

Opioid receptor antagonists may be administered in certain overdoses with non-opioids, including clonidine [21], and captopril [22]; however, the magnitude and consistency of effect are less pronounced than with its use in opioid toxicity (evidence level II-3). It is postulated that the mechanism may involve reversal of endogenous opioid peptides at opioid receptors. Naltrexone, especially the intramuscular depot form, may also be used for ethanol dependence, as it may disrupt endogenous opioid effects on the reward pathway (evidence level II-2) [23].

Studies performed in North America [1–7] and in Great Britain [8–19] in the 1950s led to the introduction and assessment of several pralidoxime salts for military purposes (protection against nerve agent exposure). Pralidoxime was first used in humans to treat organophosphorus insecticide poisoning in 1956 [20].

Pralidoxime was synthesized originally as the iodide salt, but this preparation was poorly soluble in water and produced iodism [21]. Alternatives were sought, though pralidoxime iodide remains in some pharmacopoeias and was used in Japan to treat some victims of the sarin releases [22, 23]. Pralidoxime chloride, pralidoxime mesilate (P2S), and pralidoxime metilsulfate (Contrathion™) are more soluble in water and produce fewer undesirable side effects. Pralidoxime mesilate was introduced for clinical use in the UK in 1961, and pralidoxime chloride was first licensed for use in the USA in 1964 [24]. Worldwide, pralidoxime chloride is now the most widely used pralidoxime salt.

Subsequently, obidoxime was developed by Lüttringhaus and Hagedorn [25] and von Erdmann and Engelhart [26] in an attempt to provide more effective treatment than pralidoxime for some types of nerve agent poisoning, such as tabun and soman poisoning. Obidoxime chloride (Toxogonin™) has also been employed in the treatment of organophosphorus insecticide poisoning [27].

More recently, a series of oximes were synthesized (and are known as Hagedorn or H-oximes)

by Hagedorn's group at the University of Freiburg, Germany, with the intention of increasing the specificity and spectrum of activity of oximes in poisoning with nerve agents, including soman. The most important of these oximes are HI-6 and HLö7; the latter was first synthesized by Löffler [28] in Hagedorn's laboratory. HI-6 has been studied mostly in a military context [29, 30].

The structures of pralidoxime, obidoxime, and HI-6 are shown in Fig. 1.

In clinical practice, oximes are usually administered intravenously as this is the most convenient way of achieving and maintaining satisfactory plasma concentrations. Administration by the intraosseous route produces similar results as the intravenous, at least for pralidoxime chloride [31] and HI-6 [32], and produces much faster oxime absorption than by the intramuscular route [31]. Nonetheless, the intramuscular route is still employed for self-administration (using an autoinjector) in military subjects (see below).

Clinical Pharmacology

Pharmacokinetics

Pharmacokinetic data have not been collected in neonates, children, pregnant women, or the elderly. Experimental studies are insufficient with

respect to the effects of pralidoxime in pregnancy or on fetal development. However, for organophosphorus insecticide poisoning, the risk to the mother and baby is considerable if adequate oxime treatment is not instituted promptly. This consideration should override the minor possibility that fetal damage may ensue [33].

Pralidoxime

The majority of kinetic studies on pralidoxime have been performed in healthy, non-poisoned subjects. There is evidence from animal [34, 35] and human [36] studies that organophosphorus compounds can alter pralidoxime kinetics in a complex manner; this may be due to the cardiovascular changes and reduced blood flow seen in organophosphorus insecticide poisoning. It may be inappropriate, therefore, to extrapolate the results of volunteer studies to severely intoxicated individuals.

Being quaternary amines, pralidoxime salts and obidoxime are not well absorbed after oral administration, which is why parenteral administration is used, though pralidoxime tablets were available previously. The distribution of pralidoxime is largely determined by its small molecular size and quaternary amine structure. It is thus widely distributed in most body fluids and is not significantly bound to plasma proteins [37]. Pralidoxime penetrates the erythrocyte

Table 1 Pralidoxime kinetics after intravenous dosing in volunteers

Dose mg/kg (salt)	Half-life β min	Volume of distribution (L/kg)			Study
		V_1	V_2	$(V_D)_{ss}$	
5 (chloride)	78	0.27	0.54	0.82	Sidell et al. [37]
5 (chloride)	71	0.37	0.39	0.76	Swartz and Sidell [104]
5 (chloride)	67	0.18	0.42	0.60	Josselson and Sidell [50]
5 (P2S)	84	0.20	0.58	0.78	Sidell et al. [46]
10 (chloride)	79	0.30	0.46	0.76	Sidell and Groff [45]

V_1 central compartment, V_2 peripheral compartment, $V_{d_{ss}}$ volume of distribution at steady state

membrane by simple diffusion and does not bind either to red cell stroma or hemoglobin [38]. Pralidoxime does not pass readily into the central nervous system [39]. The values for the apparent volume of distribution in the central compartment (V_1) and peripheral compartment (V_2) and at steady state ($V_{d_{ss}}$), in volunteer studies, are given in Table 1, the values at steady state being 0.6–0.8 L/kg. However, in poisoned patients treated with the metilsulfate and the chloride salts, the mean (\pm SD) volumes of distribution were found to be 2.77 ± 1.45 L/kg [40] and 2.8 ± 2.2 L/kg [36], respectively.

Pralidoxime is metabolized only to a minor extent in man [41]. It is excreted rapidly in urine [37, 42–49] and there is no evidence of dose-dependent kinetics.

As urinary clearance of pralidoxime exceeds simultaneously measured creatinine clearance, it is probable that pralidoxime is secreted by the renal tubules, at least in part, by secreting mechanisms shared by several other bases [48]. Josselson and Sidell [50] investigated the effect of intravenous thiamine hydrochloride on the elimination of pralidoxime chloride 5 mg/kg body weight administered intravenously. The addition of thiamine lengthened the elimination half-life and the oxime concentration in plasma rose, while the intercompartment clearances and rate constant for elimination of oxime fell. The authors suggested either that thiamine and pralidoxime compete for a common secretory mechanism or that thiamine alters the membrane transport of pralidoxime. Pralidoxime is preferentially excreted in an acidic urine [51], and intravenous sodium bicarbonate markedly reduces pralidoxime excretion.

Most studies, whether performed in man or animals, appear to demonstrate first-order disappearance of pralidoxime from plasma [37, 43, 52], but more complex models have also been proposed [46].

In several volunteer studies, the pralidoxime elimination half-life varied from 67 to 84 min (Table 1) after intravenous dosing of pralidoxime at 5–10 mg/kg body weight. In poisoned patients treated with the metilsulfate and chloride salts, the mean (\pm SD) elimination half-lives were found to be 3.44 ± 0.9 h [40] and 2.9 ± 1.18 h [36], respectively.

Swartz and Sidell [48] observed that in six volunteers given pralidoxime chloride 5 mg/kg body weight (but not atropine), exercise alone and exercise plus heat stress significantly ($p < 0.05$) increased the pralidoxime elimination half-life and increased the volumes of distribution in both central and peripheral compartments. This suggests that exercise and heat not only reduced the renal elimination of pralidoxime but also changed oxime distribution.

Obidoxime Chloride

Obidoxime chloride is poorly absorbed after oral administration and is therefore given parenterally. Sidell and Groff [53] reported in volunteers that the mean plasma half-life was 1.38 h after obidoxime 2.5–10 mg/kg intramuscularly. Within 24 h, 84% of the administered dose was excreted in urine [53]. In another volunteer study, a mean (\pm SD) of $68 (\pm 8)$ % of the administered dose (0.5–1.0 mg/kg intravenously) was recovered in urine in 24 h [37]. The mean (\pm SD) elimination half-life was 1.2 ± 0.16 h, the mean (\pm SD) volume of distribution ($V_{d_{ss}}$) was $0.173 (\pm 0.022)$

L/kg, and the mean (\pm SD) plasma clearance was 133 (\pm 12) mL/min [37].

In keeping with the difference in molecular weight between obidoxime and pralidoxime, the plasma concentrations versus time curves were almost identical after intravenous administration of obidoxime 1 mg/kg and pralidoxime chloride 5 mg/kg [37].

Mechanisms of Action of Oximes

Organophosphorus compounds (OPs) phosphorylate/phosphonylate the serine hydroxyl group located at the active site of the enzyme, acetylcholinesterase (AChE). The inhibition of AChE by soman is shown in Fig. 2 (see also ► Chap. 135, “Nerve Agents”). Inhibition of AChE activity occurs in the blood, brain, and other tissues in a time-dependent manner. Inhibition of AChE results in accumulation of ACh at autonomic (both sympathetic and parasympathetic) preganglionic and some central synapses and at autonomic parasympathetic postganglionic and skeletal afferent nerve endings. Consequently, ACh binds to, and stimulates, muscarinic and nicotinic receptors. Phosphorylated/phosphonylated enzyme may become “aged” by partial dealkylation of the serine group at the active site of AChE (Fig. 2). “Aging” of the phosphorylated enzyme results in an inactive enzyme, after which reactivation is no longer possible.

The fundamental action of the pyridinium oximes is to reactivate AChE inhibited by OPs (Fig. 3), thus allowing ACh to be hydrolyzed in the usual way and resumption of normal cholinergic neurotransmission. It is generally held that the beneficial effects of pyridinium oximes in OP poisoning are confined to peripheral nicotinic sites and that peripheral muscarinic and central nervous effects are clinically insignificant. Thus, the beneficial effects of oximes are mainly on neuromuscular transmission, and there is little action on muscarinic parasympathetic effects such as bronchorrhea, bronchoconstriction, and rhinorrhea. As atropine acts largely at peripheral muscarinic sites, the therapeutic combination of

oxime and atropine is well established in the treatment of organophosphorus insecticide poisoning.

Oximes are much less effective than atropine at peripheral muscarinic sites, which is why the therapeutic combination of oxime and atropine is well established in the treatment of organophosphorus insecticide and nerve agent poisoning.

Although oximes such as pralidoxime and obidoxime act primarily as acetylcholinesterase reactivators, newer oximes such as HI-6 may exert pharmacological effects unrelated to reactivation of inhibited acetylcholinesterase [54].

The reactivation of inhibited AChE by oximes and the subsequent clinical improvement depends on:

- (i) The chemical form of inhibited AChE
- (ii) The plasma concentration of the OP insecticide [55, 56]
- (iii) Aging
- (iv) The plasma oxime concentration
- (v) The duration of oxime therapy

It is commonly, but erroneously, believed that within 1 day of OP insecticide exposure, virtually all (97–99%) of the inhibited AChE is in the “aged” form rendering oxime therapy useless. However, this interpretation derives from *in vitro* studies in which AChE is rapidly inhibited and is maintained fully inhibited thereafter by the presence of an excess of inhibitor and in the absence of oxime. Such experiments do not represent the case *in vivo* and should not be used as a reason not to institute the use of oxime therapy after 24 h or to abandon its use thereafter [57, 58]. If AChE were totally inhibited, it is probable that the patient would be dead! As the clinical signs of intoxication become more severe, concentrations of acetylcholine (ACh) are increased and tend to compete with the OP oxon for the active sites of remaining uninhibited molecules of AChE. This process will reduce the rate of further progressive inhibition to a marked but undefined degree [58]. Thus, the state of complete inhibition is more difficult to reach *in vivo* than in a study of

Fig. 2 Reaction of soman (GD) with acetylcholinesterase [86]. **(a)** Soman and the active site of AChE shown together but not having undergone any reaction. **(b)** Soman combined with AChE to form an inhibitor-enzyme intermediate. **(c)** The leaving group (F) has been lost, leaving a complex of soman with AChE. **(d)** The ester link in the phosphorylated AChE has been hydrolyzed,

the enzyme has reactivated, and an alkylphosphate has been formed. **(e)** The link between the large pinacolyl group and phosphorus has been cleaved with the formation of a stable monoalkyl-phosphonylated complex with AChE and pinacolyl alcohol. This process is known as aging

Fig. 3 Reactivation of sarin-inhibited AChE by pralidoxime [86]. **(a)** Sarin has inhibited AChE by forming an esteratic bond with the hydroxyl group of a serine residue, with loss of the leaving group (F⁻): meanwhile pralidoxime forms a hydrogen bond with a histidine

residue. **(b)** A short-lived complex is formed between the inhibited enzyme and the oxime. **(c)** Pralidoxime binds to the isopropyl methylphosphonyl moiety, and the enzyme is reactivated

AChE in vitro. Furthermore, timing should not be made from the point at which first signs of intoxication are seen; these may appear, while about 50% of AChE remains uninhibited [58]. Even when signs of intoxication are marked, some spontaneous reactivation (and even some synthesis of fresh enzyme) will be going on: re-inhibition by persistent inhibitor may be less rapid than in vitro [58].

As Johnson and Vale [57] have argued, there are good biochemical and clinical reasons for suggesting that as soon as an effective concentration of oxime is achieved in vivo, the balance of aging and reactivation reaction rate for inhibited AChE is altered in favor of the latter. Progress toward complete inhibition may be slowed markedly by the use of oximes. It is probable that benefit would ensue even if oxime therapy were

started or continued several days after poisoning [59]. Oximes are of particular value in cases of intoxication from diethyl phosphates because the rate of spontaneous reactivation is very slow.

While monodealkylation occurs to some extent with all dialkylphosphorylated AChE complexes, aging is generally only of clinical importance in relation to the treatment of soman poisoning. The human in vitro aging half-life for soman-inhibited AChE is 1.3 min [60], for sarin-inhibited AChE (human in vitro data) 3 h [61, 62], and tabun-inhibited AChE (human in vitro data) 13 h. In the case of soman, therefore, once aging has occurred, recovery of enzyme function depends on resynthesis of AChE. As a result, it is important that an oxime is administered as soon after soman exposure as possible so that some reactivation of AChE occurs before all of the

enzyme becomes aged. The phenomenon of soman-induced aging led to the development of carbamate prophylaxis for nerve agent poisoning (see review of Inns and Marrs [63]). Even though aging occurs more slowly and reactivation occurs relatively rapidly in the case of other nerve agents, such as tabun and sarin, early oxime administration is still clinically important.

The dose of oxime to produce the appropriate area under the curve (AUC) of [concentration] \times [time] required to achieve the desired reactivation of phosphorylate/phosphonylated enzyme is not known with certainty. It should be noted that the AUC to reactivate a certain percentage of human AChE may well be different for human dimethyl and diethylphosphorylated enzyme. Moreover, estimates of appropriate AUCs are often derived from animal or in vitro studies with nerve agents, which are chemically distinct from OP insecticides.

Oximes are quite rapidly cleared from the body, and although some reactivation may be achieved, another cycle of inhibition (and, possibly, of “aging” of inhibited AChE) may follow. This is particularly so in the case of massive overdose where residual insecticide may persist in the body for a number of days causing a continuous release of inhibitory oxon (active metabolite) into the circulation [56]. Clearly, the initial benefit of an effective dose of oxime may be overcome by such a process, and only persistent treatment can be expected to bring about lasting clinical improvement.

Efficacy of Oximes

Animal Studies

There are consistent animal data supporting the effectiveness of oximes, when given early [4, 13, 64–69]. While pralidoxime alone can reduce the mortality in OP intoxication [4, 70–72], in combination with atropine, the protection is far greater [4, 11, 64, 66, 68, 72, 73]. The addition of diazepam to pralidoxime and atropine adds further benefit [64].

The beneficial effect of continuous oxime therapy has been shown experimentally. Oxime was

delivered by continuous infusion from implanted minipumps to rats intoxicated orally with quinalphos, a diethyl phosphorothioate with a prolonged action. Treated rats received only one small dose of atropine and diazepam plus continuous oxime for 2–4 days and were able to survive more than $30 \times$ the usual LD₅₀ dose [64].

Human Studies

Grob and Johns [74] conducted a series of experiments in volunteers in whom neuromuscular block was produced by the intra-arterial administration of a number of anticholinesterase compounds, including sarin. Pralidoxime iodide was administered either intra-arterially or intravenously. The neuromuscular block induced by sarin was “promptly and strikingly reversed in the injected extremity immediately after the intra-arterial injection” of pralidoxime iodide. Moreover, the prophylactic intra-arterial administration of the oxime protected against the action of sarin on neuromuscular transmission. Intravenous therapy was less effective than intra-arterial therapy though generalized weakness was “ameliorated” to a moderate degree following the injection of pralidoxime iodide 500–2000 mg. Muscle fasciculations were also reduced to a lesser degree than after intra-arterial injection. Approximately 20 min after pralidoxime administration, there was usually some return of weakness and fasciculation, but not to the original level.

Pawar et al. [75] administered two pralidoxime-dosing schedules in 200 patients who had moderately severe OP insecticide poisoning. Patients ($n = 100$) who received the high-dose regimen (pralidoxime iodide 2 g loading dose over 30 min, then 1 g/h for 48 h, and finally 1 g every 4 h until weaned from the ventilator) had a lower mortality (1% vs. 8%; $p = 0.03491$), less need of intubation ($p = 0.0001$), and a shorter time on ventilator support ($p < 0.0001$) than the 100 patients receiving a lower-dose regimen (pralidoxime iodide 2 g loading dose and then 1 g every 4 h until weaned). They also developed less muscle weakness and required less atropine in the first 24 h (median 6 mg vs. 30 mg; 95% CI

24–26 $p < 0.0001$) and fewer developed pneumonia ($p < 0.0001$).

Yet, the value of oximes in patients poisoned with organophosphorus insecticides has been challenged in a Cochrane Review [76] which concluded that:

Current evidence is insufficient to indicate whether oximes are harmful or beneficial in the management of acute OP pesticide poisoning. The World Health Organization recommended pralidoxime regimen (30 mg/kg pralidoxime chloride bolus followed by 8 mg/kg/h infusion) is not supported by outcomes to date. Lower doses have also shown worse outcomes in one RCT. Thus the published RCTs provide limited guidance for clinicians. Despite this, there are consistent animal data supporting their effectiveness, when given early. Based on our understanding of the mechanism, in vitro and animal data, benefit–risk ratio is more likely to be favourable when they are given early, to patients with serious poisoning by diethyl OPs. However, the RCTs have not defined effective doses or sub-groups that are likely to benefit.

The Cochrane Review [76] identified seven RCTs (845 people) in those poisoned with OP insecticides. Three of the RCTs (366 people), reported in four publications [77–80], compared pralidoxime treatment with placebo and the outcomes of mortality and ventilation requirement. Reporting of methods in the RCTs was poor. The Review noted that many studies did not account for factors that would affect outcomes. In some studies, characteristics of participants in different groups were not balanced at baseline. Only one RCT [78], comparing pralidoxime treatment with placebo, used doses of pralidoxime recommended by the World Health Organization (at least 30 mg/kg loading dose and then 8 mg/kg/h intravenous infusion) [81, 82].

In the three RCTs, oximes were given either as a dose of 4–12 g infused daily over 3 days without a loading dose or as a 2 g loading dose over 20 min followed by a constant infusion of 0.5 g/h for a maximum of 7 days. The review found no significant difference between treatment with an oxime and placebo in mortality (three RCTs: 366 people; 47/186 [25%] with oxime treatment vs. 22/180 [12%] with placebo; OR 2.68, 95% CI 0.93–7.72) or need for ventilation (three RCTs: 70/186 [38%] with oxime treatment vs. 50/180

[28%] with placebo; OR 2.00, 95% CI 0.81–4.95). The review authors noted that the different oxime doses used in the studies and differences in the types of organophosphate poison meant that meta-analysis might not produce a true estimate of effect. One of the RCTs (110 people) identified by the review also reported the proportion of people developing intermediate syndrome [79, 80]. It was found that an infusion of pralidoxime 12 g over 3 days significantly increased the proportion of people developing intermediate syndrome compared with placebo (36/55 [65%] with pralidoxime vs. 19/55 [35%] with placebo; OR 3.59, 95% CI 1.64–7.88). However, baseline differences in this RCT suggested that people allocated to treatment with an oxime might have been more severely poisoned compared with those allocated to placebo [76].

Eddleston et al. [78] came to a similar conclusion after performing a double-blind, randomized, placebo-controlled trial comparing pralidoxime chloride (2 g loading dose, followed by a constant infusion of 0.5 g/h for up to 7 days) with saline. Despite clear reactivation of red cell AChE activity in diethyl OP pesticide-poisoned patients, there was no evidence of improved survival or reduced need for intubation [78].

Why is there this discrepancy between the experimental and clinical data? In an important study performed in mini-pigs using orally administered clinically relevant doses of dimethoate EC (agricultural emulsifiable concentrate), dimethoate active ingredient alone, or solvents, Eddleston et al. [83] found that administration of agricultural dimethoate EC, but not saline, caused respiratory arrest within 30 min, severe distributive shock, and NMJ dysfunction, which was similar to human poisoning. Moderate toxicity resulted from poisoning with dimethoate active ingredient alone or the major solvent, cyclohexanone. Combining dimethoate with cyclohexanone reproduced severe poisoning characteristic of agricultural dimethoate EC poisoning. A formulation without cyclohexanone showed less mammalian toxicity. These results indicate that solvents play a crucial role in OP (and specifically dimethoate) toxicity, which could explain why oximes seem to be less effective clinically than

in experimental studies where pure OP insecticide rather than marketed formulations is often employed.

In conclusion, there are consistent animal data supporting the effectiveness of oximes when given early to treat acute organophosphate insecticide poisoning (Level 1 evidence) [84]. Results from published RCTs in humans have not shown that oximes improve outcomes when compared with placebo, but most studies have been of poor quality, so a definite conclusion cannot be drawn. The results of one study indicate that solvents may play a crucial role in organophosphorus insecticide (and specifically dimethoate) toxicity. This could explain why oximes seem to be less effective clinically than in experimental studies where pure organophosphorus insecticide rather than marketed formulations, containing solvents, is often employed. It is not known how different regimens of oximes compare to each other as there is insufficient evidence.

Which Oxime?

This is largely an academic discussion since a choice is not usually available to critical care physicians. Furthermore, for nerve agent exposures, it is unlikely that it will be known with certainty which nerve agent has been released, in a clinically relevant timeframe. Hence, the oxime most readily available should be administered in the appropriate therapeutic dose. Various experimental studies in animals have claimed the superiority of one or another oxime in the treatment of poisoning by a particular organophosphorus compound (usually a short-lived nerve agent), but comparative studies in humans have not been reported.

Between-study comparisons should recognize that plasma concentrations measured by weight per unit volume need to be converted to molar units since the molecular weights of the available oxime salts are markedly different. Thus, the molecular weights of pralidoxime chloride, pralidoxime mesilate, and obidoxime chloride are 172, 232, and 359 g/mol, respectively. Furthermore, the potency of a particular oxime depends in part on the “goodness of fit” of its molecule to the region of the active site of the

inhibited acetylcholinesterase molecule. This “fit” will be influenced by the chemistry of the particular inhibitor and will vary between compounds. Therefore, conclusions drawn from studies with one organophosphorus insecticide cannot automatically be applied to all others (or to nerve agent poisoning) although class comparisons (e.g., for diethyl phosphates) may be valid.

In the case of the treatment of OP insecticides, no difference between the efficacy of pralidoxime and obidoxime has been demonstrated, though there is some evidence that if aging is substantial, HI-6 might have an advantage. Kusic et al. [85] suggested that the general improvement in the clinical condition of poisoned patients treated with HI-6, which was more rapid than the rise of AChE activity, indicated additional beneficial effects.

Experimental studies on the treatment of nerve agent poisoning have to be interpreted with particular caution [86]. Some studies have used prophylactic protocols, whereas the drugs concerned (oxime, atropine, diazepam) would only be given to an exposed population *after* exposure. The experimental use of pyridostigmine before nerve agent exposure, though rational, is not of relevance in the civilian context.

Experimental studies in guinea pigs and monkeys have shown that pralidoxime + atropine and obidoxime + atropine were less effective in soman poisoning than HI-6 + atropine, though pralidoxime + atropine was more effective than obidoxime + atropine [87]. Studies have shown invariably that higher oxime doses, together with atropine, have increased survival further, irrespective of the nerve agent [87]. There is no clear evidence from studies in vivo that any oxime can reactivate soman-inhibited enzyme, although there is some evidence from studies in vitro that HI-6 can [86]. The evidence for the superiority of obidoxime over pralidoxime in tabun poisoning depends on studies in vivo in the mouse and guinea pig (obidoxime was not superior in the rat) and on studies using human erythrocyte acetylcholinesterase in vitro [86]. If pretreatment with pyridostigmine has not been undertaken, a review of the available experimental evidence suggests that there are no clinically important

differences between pralidoxime, obidoxime, and HI-6 in the treatment of nerve agent poisoning, with the possible exception of the treatment of GF and soman poisoning, when HI-6 might be preferred [86].

Overall, however, pralidoxime and obidoxime are the oximes of choice for civilian use in many countries as they are the most widely available and are cheaper to synthesize than HI-6. In equimolar concentrations, pralidoxime may produce fewer adverse effects than obidoxime (see below).

What Dose?

Early experiments in anesthetized cats (possibly seven animals) given lethal doses of intravenous sarin and pralidoxime mesilate 10 mg/kg intramuscularly, but not atropine, established that plasma pralidoxime concentrations of above 4 mg/L were required to counteract neuromuscular block in vitro and bradycardia, hypotension, and respiratory failure in vivo [88]. Crook et al. [89] gave dogs oral pralidoxime (mesilate and lactate) 30–115 mg/kg body weight, 1–5 h before exposure to sarin vapor. Atropine 5 mg/kg body weight was administered 1 min after the dogs were exposed to sarin. The authors extrapolated from this study in dogs to man and concluded that a plasma pralidoxime concentration of at least 3 mg/L would be required “for reasonably protective attenuation of the toxic effects of organophosphorus anticholinesterases.”

The relationship between plasma oxime concentrations after dosing with pralidoxime and obidoxime and protection against sarin poisoning has been investigated by Shiloff and Clement [69] in rats (Table 2) and by Bokonjic et al. [64] in quinalphos-poisoned rats given pralidoxime (Table 3). Taken together, these studies support the recommendation that plasma oxime concentrations of more than 4 mg/L are required to produce a significant reduction in mortality in experimental organophosphorus poisoning.

Studies in poisoned patients have shown that reactivation of dimethoate-inhibited enzyme was not achieved with a plasma pralidoxime concentration of 6.37 mg/L [55]. In the same study, it was shown that reactivation of inhibited enzyme did not occur even in the presence of a plasma

Table 2 Relationship between plasma oxime concentrations and mortality in sarin-poisoned rats also given atropine^a (After Ref. [69])

Oxime	n=	Mean (± SD) oxime concentration (mg/L)	% mortality
Pralidoxime	5	0.7 ± 0.1	100
Pralidoxime	4	2.0 ± 0.4	80
Pralidoxime	5	3.3 ± 2.3	20
Obidoxime	10	3.6 ± 0.2	90
Obidoxime	8	9.2 ± 0.6	62.5
Obidoxime	5	19.7 ± 3.7	0

^aAtropine dose, 17.4 mg/kg

Table 3 Relationship between plasma pralidoxime concentrations and LD₅₀ in quinalphos-poisoned rats also given atropine and diazepam^a (Modified from [64])

Mean (± SEM) plasma pralidoxime concentration (mg/L)	Mean (± SEM) LD ₅₀ (mg/kg)	Protective index
0	10.5 ± 3.8	—
0.8	353.6 ± 33.6	33.7
1.5 ± 0.6	457.9 ± 121.6	43.6
2.9 ± 0.7	498.7 ± 137.9	47.5

LD₅₀, median lethal dose

^aAtropine dose, 10 mg/kg; diazepam, 2.5 mg/kg

pralidoxime concentration of 14.6 mg/L when plasma ethyl and methyl parathion concentrations were >30 µg/L [55]. Data from case reports suggests that pralidoxime concentrations of >40 mg/L may be required in very severe cases of organophosphorus insecticide poisoning to produce reactivation of inhibited AChE [59, 90]. Thus, the modest doses of pralidoxime that have often been recommended in the past (to achieve plasma oxime concentrations of approximately 4 mg/L) will be insufficient to produce not only reactivation of phosphorylated enzyme but also a lasting clinical improvement, unless the patient is only mildly poisoned.

Pralidoxime chloride 30 mg/kg by intravenous injection should be administered as soon as possible in any severe or progressive case of intoxication and repeated at 4–6 h intervals; alternatively, an intravenous infusion of 8–10 mg/kg/h in an adult may be employed. These regimens are based on reported clinical studies [40, 55, 90] and

have been recommended by WHO [81] and ourselves [91]; these are Level 3 recommendations.

Based on pharmacokinetic data of obidoxime in healthy human volunteers [37], Thiermann et al. [92] considered a bolus dose of obidoxime 250 mg IV, followed by a continuous infusion at 30 mg/h, an appropriate therapeutic regimen, which they employed in single patients [27, 93] (Level 3 recommendation). The efficacy and safety of this regimen was evaluated in an observational study [94, 95]. These authors further investigated this regimen in 34 severely poisoned patients [92]. The mean (\pm SD) total dose of obidoxime infused over 65 (\pm 55) h was 2,269 (\pm 1,726) mg, which resulted in a mean steady-state plasma concentration of 5.2 (\pm 2.6) mg/L. Reactivation of inhibited erythrocyte AChE was achieved in 23 of 34 patients, while in seven patients, aging was complete before the commencement of obidoxime. In four patients, high OP insecticide load prevented significant reactivation and complete aging ensued in spite of this obidoxime regimen.

Thiermann et al. [27] reported that in parathion poisoning, obidoxime 250 mg IV as a bolus followed by 750 mg/day by infusion was effective, but that in severe poisoning, AChE reactivation did not occur until the concentration of inhibitor in the plasma had declined. The same dosage regimen was ineffective with oxydemeton methyl when oxime therapy was delayed more than 1 day after poisoning. In another series, involving parathion poisoning, reactivation was possible 7 days after poisoning, whereas with oxydemeton-methyl, a response was only seen when obidoxime therapy was instituted soon after poisoning [96]. Similarly, Zilker et al. [97] found that obidoxime (750 mg/day by infusion) reduced the need for atropine in parathion poisoning, but demeton-S-methyl poisoning only responded if obidoxime therapy was instituted shortly after intoxication.

Administration of oxime should continue for as long as inhibitory oxons (active organophosphorus compounds) are circulating, as judged clinically by the need for atropine. That is, continue therapy until clear, irreversible clinical improvement is achieved, which may take many

days while residual insecticide is cleared from the body stores.

Prolonged, high-dose treatment with pralidoxime iodide and with obidoxime chloride should be avoided, if possible, because of potential adverse effects (see below).

Which Route?

In the hospital, the intravenous route will be preferred in most cases, though the intraosseous route produces similar results as the intravenous, at least for pralidoxime chloride [31] and HI-6 [32], and produces much faster absorption than by the intramuscular route [31].

Outside the hospital, the self-administration of oxime (and atropine and a benzodiazepine) can be done conveniently by the use of an autoinjector, the contents of which are injected intramuscularly. For example, the ComboPen (UK version) L4A1 contains pralidoxime mesilate 500 mg, atropine 2 mg, and avizafone 10 mg (a diazepam precursor). The US version of the autoinjector (Antidote Treatment Nerve Agent Autoinjector [ATNAA]) contains pralidoxime chloride 600 mg and atropine 2.1 mg. Severely poisoned casualties may require the self- or buddy administration of the contents of up to three autoinjectors at 5–10 min intervals.

Adverse Effects

Pralidoxime

Sidell et al. [98] gave military personnel pralidoxime chloride 3–9 g orally; only individuals receiving 8–9 g experienced diarrhea. Volunteers were administered pralidoxime chloride, iodide, and mesilate 1.5–10 g orally [52]. Those subjects receiving the iodide salt experienced the signs and symptoms of iodism, coryza, pharyngeal burning, and painful parotid glands; consequently, the iodide salt is now rarely used. No subjective complaints were made by the volunteers ingesting pralidoxime chloride and pralidoxime mesilate in this study.

Jager and Stagg [99] found that medical students given a single dose of pralidoxime iodide

15–20 mg/kg body weight intravenously experienced dizziness, blurred vision, diplopia, impaired accommodation, headache, and nausea. Single oral doses of pralidoxime chloride 1, 2, or 4 g did not lead to changes in blood pressure or pulse, whereas the intramuscular administration of pralidoxime chloride 30 mg/kg produced a pressor response and T-wave elevation in the EKG [42]. Clinically significant EKG changes due to pralidoxime have not been observed in practice. The same dose of pralidoxime chloride given intravenously had similar effects, but pralidoxime chloride 45 mg/kg body weight also produced prolongation of the PR interval. Headache, disturbance of accommodation, and epigastric discomfort were also noted.

Volunteers, who received pralidoxime chloride daily for 6 months, tolerated the oxime well, though elevation of transaminase (aminotransferase) activity, transient lymphocytosis, and clinically insignificant EKG changes were noted in some subjects [42]. The same workers found that oral mesilate was less well tolerated than pralidoxime chloride, as it produced more gastrointestinal disturbance.

Soldiers given repeated *oral* doses of pralidoxime for 48 h experienced diarrhea (often recurrent), anorexia, and malaise [98].

Obidoxime

It has been recognized since the introduction of obidoxime that treatment for several days, particularly in high dosage, may result in liver damage, which is usually transient. Finkelstein et al. [100] have shown an association between liver dysfunction and the cumulative dose of obidoxime. The liver damage usually manifests as an increase in hepatic enzyme activities and hyperbilirubinemia [27].

Contraindications to Use

There are no absolute contraindications to the use of oximes, though it is possible that in patients with renal impairment, dosage adjustment of pralidoxime and obidoxime may need to be considered if the GFR is <30 mL/min

(Level 3 recommendation); further data are required to support this recommendation. Caution is also required when pralidoxime is administered to patients with myasthenia gravis as it may precipitate a myasthenic crisis.

Shelf Life of Preparations

Calculated shelf lives allowing for 10% degradation of 50% (w/v) pralidoxime chloride solution are 37 years, 7 years, and 1.6 years at 10 °C, 20 °C, and 30 °C, respectively [101]. Pralidoxime mesilate can be stored for at least 5 years at 5 °C with less than 7% decomposition [102]. Schroeder et al. [103] have demonstrated that an autoinjector solution (pralidoxime chloride 300 mg/mL) stored at 5 °C for more than 10 years contained more than 90% pralidoxime chloride.

D-penicillamine (DPA) is a heavy metal chelator and is the drug of choice for management of Wilson's disease, a copper-overload disease state. It may also be effective in arsenic, mercury, and lead chelation. Although the toxicity of DPA is relatively low, there are more effective and less toxic chelators, for most heavy metals, with the exception of copper. This chapter focuses on the general uses of D-penicillamine as a chelator. L-penicillamine is not used clinically due to its strong inhibition of pyridoxine-dependent enzymes, leading to neurotoxicity in animal experiments.

History

D-penicillamine is a naturally occurring base of penicillin and was discovered incidentally by Dr. John M. Walshe in the urine of a patient with liver damage who had taken penicillin [1]. Previously, Wilson's disease was experimentally being treated with various chelators including dimercaprol (British Anti-Lewsite [BAL]) and ethylenediaminetetraacetic acid (EDTA). However, adverse responses and patient intolerance led to a trial of D-penicillamine. After 1 g of D-penicillamine was tolerated without adverse effect in a dose self-administered by Dr. Walshe, the drug was given to a patient with Wilson's disease who had previously trialed BAL. The patient was given 1 g of D-penicillamine and achieved good urinary excretion of copper. From this experiment, limited

studies on murine models were conducted for preliminary toxicity reports and subsequently trialed on patients with varying stages of Wilson's Disease [2]. No formal randomized controlled human clinical trials were identified prior to the US Food and Drug Administration's (FDA's) approval of D-penicillamine in 1970, but numerous case reports supported the benefits predicted by Walshe on copper metabolism. In 1957, two case reports of D-penicillamine's effectiveness in lead chelation were published, and small controlled trials were further published in the early 1960s [3–5]. Chelation of mercury with N-acetylpenicillamine was also demonstrated in the 1950s; however, this was never widely implemented in a clinical setting.

Properties

Chemical

D-penicillamine (Fig. 1) is supplied as 3-mercapto-D-valine, having a molecular formula of $C_5H_{11}NO_2S$ and a molecular weight of 149.2 g/mol. The thiol group of this substituted amino acid leads to its ability to function as a chelator [6]. N-acetyl-D-penicillamine has a molecular weight of 191.2 g/mol. Although some benefit was reported using N-acetyl-D-penicillamine as a chelator, the result remains controversial, and it is not commercially available for medical therapy.

Physical

D-penicillamine is a white or practically white, crystalline powder supplied as a capsule or tablet. It is freely water soluble, slightly soluble in alcohol, and insoluble in ether, acetone, benzene, and carbon tetrachloride. It has a slight acetic odor and

tastes slightly bitter. The melting point of D-penicillamine is 202–206 °C (395.6–402.8 °F).

Pharmacokinetics

Kinetic characteristics of D-penicillamine in acute heavy metal poisoning have not been well described; however, information relating to pharmacokinetics of D-penicillamine in the copper-overload state associated with Wilson's disease, as well as metabolic data associated with D-penicillamine's use in rheumatoid arthritis and cystinuria, have been described in a limited number of small studies summarized in Table 1. Some additional data describing pharmacokinetics of D-penicillamine in healthy volunteers also exist [7, 8].

D-penicillamine is approved for oral administration, although intravenous and intramuscular studies have also been conducted. Formulations currently available are tablets, capsules, and a powder for liquid oral reconstitution. Oral absorption, although moderate, produces chelation results similar to those observed with intravenous administration. Therefore, oral formulations are encountered more frequently in clinical use. Absorption is significantly reduced by food, milk, and medications such as antacids and ferrous sulfate [9].

D-penicillamine is an amino acid, distributes with extracellular water and remains predominantly in the extracellular compartments. A sizeable proportion of the disulfide metabolites complex with albumin and distribute in plasma [10–12]. Approximately 80% of D-penicillamine is circulated in plasma, typically bound to plasma proteins (particularly, albumin). Oral plasma distribution of D-penicillamine begins 15–21 min

Fig. 1 Chemical structure of D-penicillamine

Table 1 Pharmacokinetics of D-penicillamine

Oral absorption: 50% (40–70% gastrointestinal tract)
Volume of distribution: 57–93 L (0.8–1.3 L/kg)
Excretion in breast milk: unknown
Clearance: primarily renal cleared as disulfide metabolites
Elimination half-life: 1–7.5 h
Cleared by extracorporeal techniques: unlikely

after ingestion with peak concentrations seen 1–4 h after ingestion. Distribution is best described by a two-compartment model. The oral volume of distribution is approximately 151 ± 31 l, with a clearance rate of $103 \pm 1 \cdot \text{h}^{-1}$. The AUC for D-penicillamine is $19.4 \pm 4.13 \mu\text{M}\cdot\text{h}$. Metabolism of D-penicillamine is not well understood, and two forms of penicillamine byproducts have been identified: penicillamine disulfide and cysteine-penicillamine disulfide. Metabolites of S-methyl-D-penicillamine have been found in the urine of patients taking therapeutic doses of penicillamine, and a small amount of metabolism, including methylation, occurs in the liver. Elimination is primarily renal and typically monophasic, although biphasic peaks have been reported in several studies. The lower molecular weight disulfide metabolites (20–30% of administered drug) are quickly excreted in the urine; however, excretion of other D-penicillamine metabolites has been reported up to 3 months after cessation of therapy in patients receiving prolonged treatment (>3 months). Approximately 30–60% of a D-penicillamine dose is excreted as unchanged drug within the first 48 h after administration. The small amount of D-penicillamine that is not excreted renally is described as free drug and is excreted in feces [6, 13–15].

The degree of chelation is dependent on the type and amount of the heavy metal present. Generally speaking, D-penicillamine is relatively safe and has a very low toxicity profile compared to other chelators, but it is unlikely to be removed by current extracorporeal methods.

Pharmacodynamics

Although D-penicillamine will bind several heavy metals, in the USA, it is only FDA approved for chelation of copper in Wilson's disease. D-penicillamine is considered first-line therapy for copper toxicity and second- or third-line treatment for lead, mercury, and arsenic toxicity [9, 16].

Optimal binding of D-penicillamine to copper ions occurs at a pH of 6.5 at a molar concentration ratio of 2:1 (D-penicillamine to Cu(II)) [17, 18].

D-penicillamine binds to cuprous (Cu(I)) ions with a slightly lesser affinity compared with cupric ions (Cu(II)), but penicillamine also has the ability to reduce copper ions and may thereby slightly increase its own binding [19].

Copper absorption ranges from 12% to 60%, depending on a variety of factors. (Copper also freely changes to and from the Cu(I) to Cu(II) states when unbound.) Copper is typically ingested in the cupric (Cu(II)) form from food and is predominantly reduced prior to transport at the basolateral surface of the intestinal cells where the Cu(I) ions are transported intracellular via copper transporter (CTR1). Humans have two ATPase copper transporters (ATP7A and ATP7B), which transport cuprous (Cu(I)) ions from the cytosol to various places, including enterocytes and hepatocytes. Once in the hepatocyte, ATP7B transports copper complexes into the trans-Golgi network where it is incorporated into ceruloplasmin and either secreted into the blood or bile. Approximately 90% of serum copper is found in the cupric (Cu(II)) valence bound to ceruloplasmin [20–22].

The therapeutic mechanism of action of D-penicillamine is not fully understood. Although there are some contradictory accounts, most reports suggest D-penicillamine competes for the cupric (Cu(II)) ions with serum albumin and ceruloplasmin (two important copper carriers), as well as acting as a reducing agent [23]. D-penicillamine is a poor competitor for freeing copper from albumin, though it mobilizes copper very well from the liver and kidney. This is in contrast to triethylenetetramine, another copper chelator, which does not enter the liver but does compete to release copper from albumin in the serum [17].

D-penicillamine also complexes with other metals including lead, mercury, and arsenic. It is suggested that lead (Pb(II)) forms a complex with D-penicillamine in a 1:1 M ratio; however, newer research suggests that several complexes can be formed at varying pHs and in molar ratios of up to 2:1 (penicillamine/Pb) [24]. Mercury (Hg(II)) is bound to penicillamine in a 1:1 M ratio at neutral pH; however, it is more effective in removing mercury from extracellular, than intracellular, compartments [25, 26]. Although clinical reports have suggested the effectiveness of arsenic

chelation with D-penicillamine [27, 28], experimental investigations have not demonstrated this effect [29, 30]. Further, D-penicillamine-As complexes have not been fully characterized.

Special Populations

Pregnancy and Breast-Feeding Patients

D-penicillamine is an FDA category D drug, demonstrating evidence of human fetal risk; however, the benefits may outweigh the risks in specific situations and therefore should not be routinely used in pregnant or breast-feeding patients. Human reports are comparable to rodent models in showing teratogenic effects including cutis laxa, arthrogryposis, and occasionally CNS defects such as corpus callosum agenesis, blindness, and hydrocephalus [31, 32]. D-penicillamine is known to cross the placenta during gestation. It is currently unknown if it also crosses into breast milk, though this is suspected. Breast-feeding is therefore not recommended when using D-penicillamine.

Contraindications

Prior to the development of pharmaceutical synthetically produced D-penicillamine, trace amounts of penicillin were found in this drug. Consequently, desensitization or avoidance was recommended in patients with penicillin hypersensitivity or allergy. Today, cross sensitivity to penicillin may still cause an allergic reaction, but the incidence of this is relatively low, and D-penicillamine should be considered if no equivalent therapeutic option is available.

Precautions

Dosing adjustments for D-penicillamine should be made in patients with severe renal impairment. Recommendations for dosing adjustment include avoidance in patients with a GFR less than 50 mL/min and thrice-daily dosing of 250 mg in patients on hemodialysis [33, 34].

D-penicillamine should not be used in combination with gold therapy, antimalarial, cytotoxic drugs, or the anti-inflammatory drugs oxyphenbutazone or phenylbutazone. Although the evidence is conflicting, some case reports describe patients who had previously developed rash with gold therapy who also developed a similar rash with penicillamine therapy [35–37]. Additional reports report gold therapy and D-penicillamine can be given in combination; however, due to the risk of myelosuppression, it is not recommended [38].

Adverse Effects

Major side effects are typically observed with chronic (>3 months) use of D-penicillamine in disease states such as Wilson’s disease, cystinuria, and rheumatoid arthritis. Little has been reported with adverse reactions related to acute, short-term exposure to D-penicillamine. The most common side effects include diarrhea (17%), dysgeusia (12%), mouth ulcers (7–13%), nausea, anorexia, proteinuria (6%), skin rash (5%), thrombocytopenia (4%), and leukopenia (2%) (Tables 2, 3, and 4).

Administration

Although previous reports describe D-penicillamine therapy with toxicities from several heavy metals, there are no widely accepted standards of therapy for heavy metals such as mercury, arsenic,

Table 2 Acute adverse reactions (exposure to D-penicillamine <3 months)

Skin	Urticaria, generalized drug rash (morbilliform, pruritic), herpetiform pemphigus
GI	Nausea, diarrhea, vomiting, colitis, dysgeusia
Heme	Agranulocytosis
Rheum	Polymyositis, DPA-induced lupus erythematosus-like syndrome
Neuro	Dystonia, extrapyramidal symptoms
GU	Proteinuria, nocturnal enuresis
Pulm	Bronchospasm, rhinitis
Other	Drug fever

Table 3 Adverse reactions in chronic exposure (exposure to D-penicillamine >3 months)

Skin	Elastosis perforans serpiginosa, nail damage, pemphigus, late generalized rash
Endo/metabolic	Zinc deficiency, copper deficiency, gynecomastia
Heme	Leukopenia, thrombocytopenia
Immune	Myasthenia gravis and ocular myasthenia gravis
Renal	Goodpasture's syndrome, kidney disease including acute renal failure and nephritic syndrome, nephrolithiasis
Pulm	Alveolar pneumonopathy, dyspnea, pleural effusions, pulmonary hemorrhage

Table 4 Dose relation to adverse reactions to D-penicillamine exposure

Dose related	Non-dose related
Cheilosis	Glomerular nephritis
Gingivostomatitis	Nephrotic syndrome
Glossitis	
Stomatitis	
Mouth ulcers	
Extrapyramidal symptoms	

or copper in acute toxicity. While D-penicillamine chelation therapy has been used with lead, clinical evidence demonstrates there are more effective lead chelators available, including succimer and EDTA. The American Academy of Pediatrics Committee on Drugs considers D-penicillamine to be a third-line agent for chelation therapy in lead toxicity [39].

Copper Toxicity

As noted, D-penicillamine is useful in managing copper-overload states such as Wilson's disease and is an effective copper chelator (Grade II-2 evidence). The typical initial adult dose is 1,500–2,000 mg daily in two to four divided doses and decreased to 750–1,500 mg/day (divided doses) for maintenance therapy. The objective is to increase urinary copper excretion to more than 2 mg/24-h urine, and treatment is usually continued for approximately 3 months.

The pediatric dose is 15–30 mg/kg/day in two to four divided doses [40].

Lead Toxicity

According to the US Centers for Disease Control and Prevention (CDC), chelation therapy should be initiated in adults with blood lead levels exceeding 100 µg/dL(4.8 umol/L) [41]. Reports of up to 2 g per day of oral D-penicillamine have been administered; however, no large randomized controlled trials have been reported. In a more recent publication, Cuprimine (D-penicillamine) that was given at doses of 25–35 mg/kg/day in divided doses showed an increase of lead excretion (short term) by 20–30 times the average daily excretion [42, 43].

While the CDC does not recommend chelation therapy for blood lead concentrations below 45 µg/dL (2.2 umol/L), case reports have shown some benefit of D-penicillamine for blood lead levels between 25 and 45 µg/dL (1.2–2.2 umol/L). A dose of 15 mg/kg/day demonstrated benefit in reducing by half the original blood lead level in children (Grade II-3 evidence). Up to 30 mg/kg/day has been administered with minimal adverse effect [44, 45].

Mercury Toxicity

D-penicillamine increases mercury excretion and decreases body burden in animal studies with inorganic mercury poisoning [46, 47]. A few case reports in children have also alluded to efficacy for mercury chelation [48–50]. If used, the dose for children and adults is similar to that used in lead chelation.

Arsenic Toxicity

While its efficacy has not been proven in animal studies, D-penicillamine can enhance the renal excretion of arsenic in humans. However, efficacy is higher with other chelating agents resulting in D-penicillamine from being used for the heavy

metal poisoning. If used, the dose for children and adults is similar to that used in lead chelation.

Decorporation therapy is based on the principle that accelerating the excretion of internalized radioactive materials results in fewer acute adverse acute and long-term health consequences. Reducing the amount of radioactive material inside the body, and the duration of its residence in proximity to cells and organs, reduces the committed effective dose of ionizing radiation delivered to these tissues. The committed effective dose is estimated from intake of the radioactive material over 50 years for adults and to age 70 years for children [1].

For over five decades in both the United States and Europe, diethylenetriaminepentaacetic acid (pentetic acid; DTPA) has been used to treat individuals internally contaminated with actinide elements by enhancing the renal clearance of these radionuclides [2]. Pentetic acid is compounded into a salt with either calcium or zinc forming chemically stable and water-soluble actinide chelates which are easily excreted in the urine. The US Food and Drug Administration (FDA) has approved both Ca-DTPA and Zn-DTPA formulations for the removal of the actinide elements plutonium (Pu), americium (Am), and curium (Cm). (Fig. 1).

Although, this chapter will focus on the management of internal contamination of Pu, Am, and Cm (which are FDA-approved indications), there is evidence that DTPA can be used in the medical management of internal contamination with a number of other radioactive elements, according

Fig. 1 1 g/5 ml vials

to the National Council on Radiation Protection and Measurements (NRC) [3] (see Table 1).

Properties

There are two formulations of DTPA (Fig. 2): a calcium and a zinc salt. The calcium salt has an empirical formula of $\text{Na}_3\text{CaC}_{14}\text{H}_{18}\text{N}_3\text{O}_{10}$ and a molecular weight of 497.4 g/mol. The zinc salt has an empirical formula of $\text{Na}_3\text{ZnC}_{14}\text{H}_{18}\text{N}_3\text{O}_{10}$ and a molecular weight of 522.7 g/mol [4]. Both salts are formulated in sterile water for injection as clear, colorless, and odorless liquids.

Pharmacokinetics

Both calcium and zinc DTPA salts form chemically stable, water-soluble chelates when combined with actinide metals that can then be excreted in the urine [5]. Calcium and zinc DTPA have a 100% bioavailability when administered intravenously. They are incompletely absorbed when administered orally or by inhalation (less than 10% and 20–30% respectively), although there is an increasing number of animal

studies evaluating the safety and efficacy of orally administered DTPA formulations [6–8].

A small portion of DTPA (10%) binds to plasma proteins resulting in somewhat delayed elimination. However, the elimination half-life is typically 20–60 min. Renal excretion by glomerular filtration is the primary mechanism of elimination, with a very small percentage (<3%) excreted in the feces [4].

Administration

The use of DTPA is indicated when internal contamination with Pu, Am, or Cm is sustained by inhalation, ingestion, or injection (e.g., through a wound). Contamination with radioactive material most commonly occurs in occupational settings (e.g., nuclear weapons facilities or nuclear power plants) but can also affect large populations in the setting of the detonation of a radioactive dispersal device in wartime or terrorist acts [4, 9].

Possible Source of additional information: <http://emergency.cdc.gov/radiation/contamination.asp>

The efficacy of DTPA has been studied in animals where it has been shown to decrease the uptake of Pu from liver, bone, and lungs and decrease the incidence of radiation-related bone tumors. Efficacy in humans is based on registries of patients suffering occupational exposures in the United States, Europe, and Russia [4].

Calcium DTPA is considered to be approximately 10 times more efficacious than its zinc counterpart in the first 24 h after internal contamination. Unfortunately, the evidence to support this statement has not been published. Nonetheless, if additional chelation therapy is required or if treatment is initiated after the first 24 h, it is preferable to use zinc DTPA because it has fewer adverse effects [10].

The duration of therapy is dependent on the amount of radioactive material present inside the body and the response to therapy. Treatment can be monitored by measuring radionuclide excretion in the urine using 24-h collection. In several published cases, DTPA therapy was used for multiple doses without statistically or clinically significant adverse effects (Grade III evidence). Most

Fig. 2 Molecular structure of DTPA

individuals require a few doses although some require much more extensive therapy in order to minimize as much as possible the dose delivered by the radionuclide to the organs. There is a documented case of an individual being treated over 4 years with a total of 245 doses [11].

Therapy should be initiated as soon as possible after exposure as DTPA chelation is most effective when the actinide elements are circulating in the blood. As tissue and solid organ deposition of the actinide progresses, the efficacy of chelation therapy decreases.

The standard dosing of DTPA is: 1 g every 24 h administered continuously over 30 min in 250 ml of D5W, Lactated ringer's or normal saline. Parenteral administration is the best studied; and this

route has been shown to be the most efficacious (Grade III evidence). However, there are numerous animal studies that suggest oral administration may also be useful in the setting of mass casualty or ingestion exposures [7, 8, 12, 13].

For internal contamination from inhalation, nebulized calcium or zinc DTPA therapy may be preferred in adults [14] (Grade III evidence). The dose is 1 g calcium or zinc DTPA diluted in a 1:1 ratio with sterile water, administered as a nebulized treatment over 15–20 min. If continued decontamination is indicated after the first dose of nebulized Ca-DTPA, the patient should receive Zn-DTPA parenterally for the remaining doses [12].

Wounds grossly contaminated with radioactive materials may be irrigated with a solution that

contains 1 g calcium or zinc DTPA and 10 ml 2% lidocaine in 100 ml of normal saline [4].

It is important to note that radioactive materials are excreted in the feces and urine, and these body substances should be treated as such. Care should be taken by healthcare workers to avoid radiation exposure when disposing of these radioactive bodily fluids.

Special Populations

Renal Failure

DTPA therapy is still a viable option for patients with renal failure as the chelate can be dialyzed. The dialysate will be radioactive and must be disposed of accordingly.

Pregnancy and Breastfeeding

Both salts of DTPA are listed as FDA Category C medications, meaning some evidence of teratogenicity was present in animal, but not in human, studies. Limited evidence in animal models supports the administration of zinc DTPA instead of calcium DTPA [15, 16]. It is important to note radionuclides can be excreted in breast milk. Lactating mothers should follow their physician's and public health official's recommendations about breastfeeding after a radiation emergency.

Children

Current prescribing information recommends dosing 14 mg/kg with a maximum of the adult dose of 1 g every 24 h. This dose was extrapolated from the adult dose [13]. Nebulized calcium or zinc DTPA has not been tested in children.

Adverse Effects

Calcium and zinc DTPA are generally well tolerated. DTPA chelates many metals, the most clinically relevant being zinc cadmium, manganese,

Table 2 Reported adverse effects

Allergic cutaneous reaction	Chills	Headache
Nausea, vomiting	Diarrhea	Reversible anosmia
Subjective weakness	Pruritis	Cough/wheezing from nebulized calcium DTPA

iron, copper, lead, and vanadium. As such, zinc, magnesium, and manganese deficiencies have been reported with calcium DTPA [10]. These complications are easily reversed with supplementation with therapy during treatment. Zinc DTPA does not result in zinc deficiency, but it can cause magnesium deficiency, and patients should be monitored for this complication [17]. As reported in the drug label, three deaths occurred in patients with severe hemochromatosis who were treated with daily intramuscular calcium DTPA to remove iron. These three patients received 4 g of calcium DTPA per day. The first patient had received 14 g before death and the other two had been treated for 2 weeks [12].

Other adverse effects reported in various publications are listed in Table 2 [1]. Based on the US registry that included 646 individuals who received either calcium or zinc DTPA, 20 adverse events were reported and these were primarily in patients receiving the calcium salt [12].

Acknowledgments The authors wish to acknowledge Dr. Johann Ruprecht and Mr. Alexander Heyl, Heyl Chemisch-pharmazeutische Fabrik GmbH & Co. KG Berlin for their collaboration during the authorship of this chapter.

Physostigmine salicylate (Antilirium®) is a short-acting, lipid-soluble, nonselective, carbamate cholinesterase (ChE) inhibitor used to increase acetylcholine (ACh) concentrations at cholinergic receptors and most commonly employed in the treatment of anticholinergic-induced delirium. Physostigmine was the first known anticholinesterase used by humans. The native Efik people of West Africa used dried, ripened Calabar beans (*Physostigma venenosum*) containing the alkaloid physostigmine in their “trial by ordeal” [1, 2]. First described in 1840, the Old Calabar “trial by ordeal” required an accused individual to consume 1–20 Calabar beans in various fashions. If the individual vomited (and thus cleared the gastric bean burden), he was deemed innocent; if emesis did not occur, a cholinergic crisis followed by death was considered a guilty verdict. Predictably, very few accused survived their ordeal [1].

In 1863, ophthalmologist Argyll Robertson described the first clinical use of Calabar bean extract to reverse the mydriatic effects of atropine. In 1864, the first clinical use of physostigmine as a systemic antidote was described in four prisoners who became severely anticholinergic after drinking bottles of atropine they mistook for alcohol. Kleinwachter, the prison physician, gave the most severely poisoned patient Calabar bean extract orally as an experiment. Although the physostigmine extract promptly made him vomit, it also resulted in

rapid return to baseline cognition. The less severely poisoned prisoners did not receive the Calabar bean extract, and took longer to recover [2].

The clinical use of physostigmine as an antidote did not become popular until nearly a century later. In 1958, 4 mg of physostigmine by injection was reported to be “entirely effective” in reversing iatrogenic coma induced by 32–212 mg of intramuscular atropine, where “by 20 min there was complete restoration of the patient’s pretreatment psychophysiological status” [3]. In 1967, physostigmine (0.05 mg/kg, intramuscularly) given for iatrogenic scopolamine toxicity reportedly resulted in “dramatic, rapid improvement, which was noticeable at 10 min and maximal at 30 min, at which time [they] were alert, coherent and well-oriented” [4]. Also in 1967, 1–2 mg of parenteral physostigmine was reported to reverse central anticholinergic effects of antiparkinsonian drugs promptly in 26 consecutive patients [5, 6]. In 1970, successful use of physostigmine for tricyclic antidepressant (TCA) overdose was first reported, reversing amitriptyline-induced agitation in a toddler with a “normal” ECG [7]. For the next decade, physostigmine was commonly recommended for

TCA-induced agitation and cardiovascular toxicity. However, in 1980 a controversial case report was published by Pentel and Peterson in which two patients developed recurrent seizure and severe cardiotoxicity after intentional tricyclic antidepressant overdose. Both patients developed a widened QRS duration progressing to bradycardia and heart block. Physostigmine was administered to each without improvement in cardiotoxicity. Atropine was then administered, followed shortly by asystole. Sodium bicarbonate was never administered. The authors concluded that, due to the temporality of the events, physostigmine was causative of asystole [8]. Though their conclusions were challenged in the literature [9], there was, nonetheless, a dramatic decline in the use of physostigmine, especially in cases of TCA toxicity, despite an overall increase in the number of reported cases of anticholinergic toxicity (Table 1) [15–17].

Clinical Pharmacology

The neurotransmitter acetylcholine (ACh) is necessary for all preganglionic autonomic neurons and postganglionic parasympathetic neurons and

some postganglionic sympathetic neurons. During basal states, there is a low level of ACh release from these neurons. After release, ACh is catabolized by synaptic acetylcholinesterases (AChEs). There are two types of cholinesterases (ChEs): (1) tissue or acetyl and (2) plasma, pseudo, or butyryl (BuChE). Circulating ACh from ingested foods and various medications, such as various choline esters, succinylcholine, and cocaine, are BuChE substrates. Synaptic ACh is the primary substrate for AChE and rapidly deacetylates the neurotransmitter [18].

Acetylcholine and physostigmine bind to the same site on ChEs. Acetylcholine acetylates cholinesterase and physostigmine carbamoylates cholinesterase. After hydrolysis (deacetylation or decarbomoylation) of the enzyme, the cholinesterase is regenerated. Because hydrolysis occurs rapidly (150 ms) for acetylated cholinesterase, the effect of ACh is dissipated before the end of the refractory period of the postsynaptic potential. In contrast, decarbamoylation takes 15–30 min [19]. Physostigmine reversibly inhibits the degradation of ACh, resulting in synaptic accumulation and repetitive, asynchronous stimulation of neighboring cholinergic receptors. Excess postsynaptic cholinergic receptor stimulation may result in sustained depolarization and subsequent blockade, leading to weakness or paralysis. Excess presynaptic cholinergic receptor stimulation may induce antidromic firing of the motor neuron, leading to fasciculations [19]. Clinically, reversible inhibition of ACh metabolism by carbamoylation lasts 3–4 h [19]. In the setting of anticholinergic toxicity, the intended function of physostigmine is to reverse cholinergic receptor antagonism and normalize cholinergic tone.

The primary pharmacological, toxicologic, and antidotal effects of physostigmine result from increased ACh stimulation of muscarinic and nicotinic cholinergic receptors. Physostigmine is a nonselective cholinesterase inhibitor, thus exhibiting efficacy at cholinesterases throughout the body. The physiologic effects of physostigmine, which are the result of decreased ACh breakdown, are listed in Table 2. Physostigmine’s cardiac properties are complex, due to mixed effects from muscarinic and nicotinic

Table 2 Physiologic effects of physostigmine

Receptors	Organ system	Clinical effects
Muscarinic	Exocrine	Salivation, lacrimation, perspiration, bronchorrhea

	Ocular	Mydriasis
	Muscle (neuromuscular junction)	Muscle cramps, weakness, fasciculations, tremor, flaccid or rigid paralysis

CNS central nervous system

stimulation [20]. Muscarinic stimulation leads to increased conduction time at the sinoatrial and atrioventricular nodes, bradycardia, and diminished cardiac output, whereas nicotinic stimulation has the opposite effects. In one study of “anticholinergic” overdoses, physostigmine led to significantly increased mean arterial pressure (MAP) and cardiac output [21]. In a dog model of amitriptyline poisoning treated with physostigmine, cardiac output was increased, but systolic blood pressure and heart rate largely remained unchanged. These data, collected through controlled experimentation, conflict with the clinical case report of Pentel and Peterson published at roughly the same time [22].

The vasodilatory effects of physostigmine are mediated by ACh-stimulated presynaptic inhibitory receptors on vascular sympathetic fibers and

inhibitory vascular cholinergic receptors. Stimulation of the inhibitory vascular cholinergic receptors leads to release of endothelium-derived relaxing factor, resulting in smooth muscle relaxation and vasodilation [18]. In patients treated with the anticholinergic agent methscopolamine, who then received 0.022 mg/kg (≤ 2 mg) of intravenous (IV) physostigmine over 10 min, significant increases in blood pressure, heart rate, and serum epinephrine levels were observed [18, 23]. Physostigmine's catecholamine-releasing effects seem to be centrally mediated [23]. In contrast, neostigmine is an anticholinesterase that does not cross the blood–brain barrier and does not increase serum epinephrine levels. Scopolamine, a centrally acting anticholinergic, blocks the ability of physostigmine to increase serum epinephrine levels.

While physostigmine is often said to possess nonspecific CNS arousal properties, the origin of this concept stems primarily from various individual case reports or small case series in which physostigmine has been used to reverse sedation due to hepatic encephalopathy and many nonanticholinergic drugs, including barbiturates, benzodiazepines, ethanol, droperidol, volatile anesthetics, ketamine, opiates, and propofol. Various mechanisms of this nonspecific arousal have been proposed from these anecdotal reports without validation [24, 25]. Results from higher-quality randomized clinical trials have not conclusively supported these claims, and the data are conflicting, with some authors supporting [26–33] and others refuting [34–37] this concept. Therefore, the literature does not clearly endorse the use of physostigmine as a nonspecific arousal agent in the absence of true antimuscarinic-induced CNS alteration.

Chemical and Physical Properties

Physostigmine (Fig. 1) is a tertiary amine carbamate. At physiologic pH, this tertiary amine is in equilibrium between charged and uncharged forms, with the uncharged species readily crossing the blood–brain barrier [19, 20]. In contrast, neostigmine methylsulfite and pyridostigmine bromide, the other injectable anticholinesterases,

contain an ammonium ion (a cationic quaternary amine), inhibiting the ability of these compounds to cross the blood–brain barrier.

Physostigmine has a pK_a of 7.9; a 0.5% aqueous solution has a pH of 5.8 [38]. At physiologic pH, it exists primarily as a cation. Physostigmine is unstable at room temperature and should be stored in light-resistant packages at temperatures between 15 °C and 30 °C [36]. The solution develops a red tint when exposed to metals or with prolonged exposure to heat, light, or air and should not be injected if it is more than slightly colored [38].

Metabolism

Physostigmine is primarily metabolized through hydrolytic cleavage by acetylcholinesterase and other true cholinesterases [39]. Renal excretion is only a minor factor in physostigmine clearance. The pharmacokinetic profiles of physostigmine have received very little human study with

significant discrepancy between the two studies. Though not touched upon by the authors, the discrepancies are likely related to very different methodologies employed [40, 41].

Pharmacodynamics

Traditionally, physostigmine was thought to have very rapid onset of action after intravenous administration, with early literature suggesting an onset of action of 2 min and peak effect 5 min after intravenous administration, onset 23–30 min after intramuscular use [42]. These reported kinetics likely drove early use of recommendations of re-dosing intravenous physostigmine every 5 min. However, more recent rat, dog, and nonhuman primate studies using radio-labeled physostigmine suggest that peak cortical cholinesterase inhibition is delayed for up to 20–30 min following intravenous administration [43–45]. In the above-noted human pharmacokinetic studies by Asthana and Hartvig, the elimination half-life of physostigmine was noted to be approximately 15–20 min. However, central cholinesterase inhibition extends far beyond the simple plasma half-life of physostigmine, with numerous animal studies demonstrating continued inhibition of acetylcholinesterase (as a marker of physostigmine activity) lasting well beyond 100 min [40, 46–48]. This is fitting with clinical reports suggesting a duration of action of 30 min to several hours after intravenous physostigmine administration [4, 5, 42, 49]. Consequently, the dosing frequency recommended in early case series and case reports that may be more aggressive than the more recent data suggest is required and may result in inadvertent dose stacking. No well-controlled human trials exist with respect to variations in dosing frequency for physostigmine.

Contraindications

Cardiotoxicity

Recommendations regarding the use of physostigmine in the setting of anticholinergic-induced cardiotoxicity are conflicting. This discussion is

clouded by the cultural change in the use of physostigmine following the case report by Pental and Peterson, which limited availability of more modern clinical data. Although some authors recommend physostigmine only for anticholinergic toxicity without serious cardiovascular toxicity [50], others recommend it only for cases of anticholinergic toxicity with serious cardiovascular toxicity [51, 52]. Although the cautious approach is to consider seizures, hypotension, intraventricular or atrioventricular heart block, bradycardia, and ventricular dysrhythmias to be contraindications to physostigmine use, large case series and animal data argue against this position [49, 50, 53, 54]. Since the publication of Pental and Peterson's report, the conversation regarding the indications and contraindications of physostigmine use has divided into two separate discussions: TCA-induced cardiotoxicity and non-TCA-induced cardiotoxicity. It has become dictum in the emergency medicine culture to avoid physostigmine in the setting of TCA-associated QRS widening, despite meager and contradictory evidence [55]. However, a historical review of the evolution of physostigmine use in TCA toxicity reveals conclusions based on an incomplete understanding of the mechanisms of TCA toxicity and the therapeutic goals of physostigmine administration.

Routine practice of TCA-induced cardiotoxicity in the late 1970s and early 1980s did not involve usage of hypertonic sodium administration (e.g., sodium bicarbonate). During this era, TCA overdose conferred high mortality due to what was interpreted to be atropine and quinidine-like effects. The anticholinergic properties of TCAs prompted exploration of physostigmine as an antidote, which resulted in clear reversal of central anticholinergism [16, 56]. Case reports and small animal studies were subsequently published that suggested physostigmine may positively affect TCA-induced cardiotoxicity [57, 58]. It is important to note that the cardiotoxicity of TCAs is complex. Tachycardia may be related to a combination of antimuscarinic effects, inhibition of norepinephrine, and/or peripheral vasodilation. These effects may also be seen in concert with cardiac myocyte sodium channel blockade that

may result in widened QRS duration and other conduction abnormalities. Clearly, these are entirely different mechanisms of effect. Certainly, the antimuscarinic-driven tachycardia may be reversed by physostigmine. Indeed, it was tachycardia in TCA-poisoned patients that was the focus of the early cardioprotective claims of physostigmine, which was postulated to enhance vagal tone, which in turn, resulted in decreased tachycardia [56]. However, intraventricular conduction delay or profound bradycardia, which is an ominous sign of severe toxicity, was rarely present in these reported cases. These features of cardiotoxicity are not related to antimuscarinic effects, but instead related to the dose-dependent degree of sodium channel blockade – a mechanism entirely separate from the mechanisms inducing tachycardia [57]. To suggest that physostigmine reverses all aspects of TCA-induced cardiotoxicity may be erroneously generalized. From a pharmacologic perspective, it is unclear why enhancement of vagal tone should improve TCA-induced intraventricular conduction delays [59]. In fact, controlled experimental animal data has demonstrated no significant effect on either lengthening or shortening of QRS duration in TCA poisoning or non-poisoned controls, even with massive doses that induced signs of cholinergic excess [59, 60]. Larger human case series have provided support to these findings, with no evidence of cardiac conduction delay being induced or worsened by physostigmine in the treatment of TCA or non-TCA-induced altered mentation [50, 54].

Many emergency medicine and toxicology texts have recommended against usage of physostigmine in the setting of TCA overdose or prolonged QRS durations [55]. However, these recommendations stem from the same flawed understanding of the goals of physostigmine therapy noted above. Though various texts and articles suggest withholding physostigmine in the setting of widened QRS duration of >100 ms, the origin of this threshold does not appear to be experimentally derived and may instead be based on the clinical characteristics of the few case reports in the literature [55]. This threshold may also be an extension of the work of Boehnert and Lovejoy in which TCA-induced seizure occurred

with QRS durations ≥ 110 ms, though cardiac arrhythmias only occurred once the QRS duration was ≥ 160 ms [61]. Baseline QRS durations are physiologically variable. In a study of 1,254 healthy white males, the baseline QRS duration was defined as <120 ms (range from 80 to 116 ms) [62].

Based on the most recent assessment of the literature, the data suggest that physostigmine is not indicated for the specific treatment of intraventricular conduction delays, advanced heart block, or profound bradycardia in the setting of TCA or other anticholinergic overdoses. This is due in part to the lack of pharmacological effect of physostigmine on sodium channel conduction and in part due to more effective alternatives to management (grade II recommendation). Given that hypertonic sodium administration and serum alkalization are safe and effective for reduction of QRS widening due to sodium channel blockade attributed to cyclic antidepressants and certain other anticholinergic agents, the primary role of physostigmine in the management of this specific situation is further diminished [63–73].

Seizures

Seizures may be caused by both anticholinergic agents as well as cholinergic excess, making it difficult to separate seizure activity due to physostigmine from the natural course of the anticholinergic toxicity. In a case series of 41 patients who overdosed on maprotiline (a tetracyclic antidepressant with high seizure potential), 15 patients seized, only half of which were preceded by physostigmine use (dose not reported) [74]. Vance et al. reported seizure induction in all mice with TCA toxicity treated with physostigmine. However, the doses used were equivalent to nearly half the LD_{50} of physostigmine in these mice, arithmetically equating to an adult human dose of roughly 20 mg [55, 75]! More externally valid data from large human case series as well as double-blind rat studies demonstrate no increase in seizure rate with typical physostigmine doses in the treatment of anticholinergic toxicity [50, 76]. However, physostigmine should be used cautiously in those who have had a seizure, as this may indicate a propensity to seize in

response to the specific agent of overdose, which may be further potentiated by physostigmine administration (grade III recommendation).

Asthma

A history of asthma is noted as a contraindication to physostigmine in the package insert [38]. While bronchial hyperreactivity has occurred when physostigmine was given via nebulization to asthmatic subjects [77], the clinical relevance of this in the setting of anticholinergic toxicity is likely limited. In a series of 45 patients with anticholinergic poisonings given physostigmine, none of the 12 patients with a history of asthma developed bronchospasm [50]. Logic dictates that physostigmine should not be given to anyone with an active asthma exacerbation. However, as bronchodilation is a manifestation of anticholinergic toxicity, it is unlikely that the combination of anticholinergic toxicity and active asthma exacerbation will be clinically encountered.

Sodium Bisulfite Sensitivity

The product insert for physostigmine also cautions against administration of patients with known sensitivity to sulfur or sulfites, because the vehicle for parenteral physostigmine salicylate contains sodium bisulfite [38]. The true prevalence of sulfite allergy is unknown, and there is great variation in allergic response. As historical and allergy information is likely to be extremely limited in the setting of altered mentation due to anticholinergic toxicity, this can only be considered a relative contraindication to use. It is important to note that a sulfite allergy is not synonymous with the more common “sulfa” or antibacterial sulfonamide allergy in which susceptible patients react to the specific sulfur-containing sulfonamide moiety. There is no cross allergenicity between antibiotic sulfonamides and other nonantibiotic sulfur-containing agents, including sodium bisulfite [78].

Other Contraindications

Other traditional contraindications to cholinergic agents include coronary artery disease, gangrene, gastrointestinal or urogenital obstruction, diabetes, and use of other cholinergic medications

[38]. The clinical significance of physostigmine with these comorbidities in the setting of anticholinergic toxicity is unknown.

Treatment

Indications for physostigmine use can be broken up into three treatment categories with various levels of efficacy and potential risks: anticholinergic-induced agitation, cardiotoxicity, and CNS toxicity.

Anticholinergic-Induced Delirium

The US Food and Drug Administration-labeled indication for physostigmine is reversal of central anticholinergic toxicity [38]. Successful use of physostigmine to reverse central anticholinergic toxicity caused by over 700 different anticholinergic drugs and plants has been anecdotally reported [79]. In the largest published case series to date, Burns et al. retrospectively reviewed 52 laboratory-confirmed anticholinergic poisonings (including four TCAs) in a blinded fashion and noted that physostigmine controlled agitation in 96% of patients and completely reversed altered mentation in 87%. By comparison, benzodiazepines only controlled agitation in 26% of patients with no effective reversal of altered mentation. Additionally, those receiving physostigmine had a lower incidence of aspiration, lower rate of endotracheal intubation, and shorter mean time to recovery [50]. Watkins et al. demonstrated that in all-cause antimuscarinic-induced delirium, the use of physostigmine alone resulted in a significant reduction in the rate of intubation compared to other treatment groups (1.9% vs. 8.4%) [54]. Multiple smaller case series also confirm the superiority of physostigmine to benzodiazepines in pure antimuscarinic agitation without occurrence of significant adverse side effects [53, 80, 81]. Further indications for the use of physostigmine are anticholinergic toxicity with hyperthermia and hemodynamically significant sinus tachycardia. The goals of physostigmine therapy in these cases are to treat hyperthermia, to avoid

emergent intubation (needed to protect the airway) and artificial ventilation (in order to treat excess respiratory depression from sedatives), and to control behavioral abnormalities and rhabdomyolysis (caused by agitation and restraints).

Central anticholinergic toxicity is usually, but not always, accompanied by signs of peripheral anticholinergic toxicity and may be difficult to diagnose clinically (see ► Chap. 23, “Anticholinergic Syndrome”). In cases of marked delirium in which anticholinergic agents are suspected, published literature demonstrates safety of using physostigmine as a diagnostic test [42, 53, 80, 82] (grade III recommendation).

Anticholinergic-Induced Cardiotoxicity

Controversy abounds with respect to the utility of physostigmine to manage xenobiotic-induced cardiotoxicity. Effective discussion of anticholinergic-induced cardiotoxicity must differentiate between management of all-cause anticholinergic-induced tachycardia and TCA-induced cardiac conduction abnormalities.

The use of physostigmine for anticholinergic-induced tachycardia has received little direct study. Instead, research has focused on management of delirium from antimuscarinic agents. However, heart rate trends are often presented in the data which demonstrate a consistent decrease in mean heart rate and increased MAP without induction of symptomatic bradycardia. This holds true even in the setting of non-TCA-induced conduction abnormalities, such as can be seen in large diphenhydramine overdoses, for example [50, 53, 80].

With respect to TCA-induced cardiotoxicity, the discussion must be tailored around the etiology of the cardiotoxicity that is intended to be managed by physostigmine. While there exist various individual case reports where TCA-induced “cardiotoxicity” resolved after physostigmine use, these case reports often do not differentiate between types of cardiotoxicity treated (be it simple tachycardia, advanced heart block, or profound bradycardia), nor is physostigmine the sole agent employed for treatment

[21, 83–85]. Indeed, the quality of these reports is no better than the controversial report by Pentel and Peterson. Additionally, multiple animal models of TCA-induced cardiotoxicity demonstrate variable efficacy of physostigmine in correcting conduction abnormalities, often utilizing doses of many orders of magnitude beyond those typically used in human treatment and limiting external validity [73–77]. With respect to simple TCA-induced tachycardia (in the setting of altered mentation), the literature demonstrates physostigmine’s efficacy in heart rate reduction [16, 56].

However, with respect to TCA-induced sodium channel blockade, physostigmine serves no logical role. In a well-designed randomized, controlled study, Goldberger and Curtis induced QRS widening in rabbits using amitriptyline. In those given a massive dose of physostigmine, there was neither narrowing nor widening of QRS duration, despite a decrease in heart rate and induction of cholinergic signs [59]. Lum et al. also demonstrated that physostigmine had no influence in heart rate or QRS duration in cats, both in the setting of pretreatment with a large dose of physostigmine and in the setting of nortriptyline-induced sodium channel blockade [60].

Regardless, as noted previously, the safety and efficacy of hypertonic sodium administration and serum alkalization in TCA cardiotoxicity likely supplant any role of physostigmine for this toxicity [64–73].

Anticholinergic-Induced Seizures

Given that seizures are frequently seen in both anticholinergic toxicity and following excessive or unnecessary physostigmine administration, physostigmine is not indicated for seizure management. Human evidence for or against this recommendation in case reports and series is limited due to the characteristic abrupt onset of seizures with severe anticholinergic toxicity and the difficulty distinguishing the temporality of seizure induction or reversal with the variable-dosing regimens of physostigmine. However, in one double-blind rat model addressing this question, no therapeutic benefit of physostigmine was seen

in diphenhydramine-induced seizures compared to controls [76].

Gamma-Hydroxybutyrate-Induced Sedation

There exist several recommendations in the literature for the usage of physostigmine to reverse the profound sedation of gamma-hydroxybutyrate (GHB) intoxication. In the 1970s, two poorly designed studies reported that physostigmine could be used safely and effectively to reverse sedation from GHB used as an anesthetic agent [86, 87]. One author anecdotally reported the safe and effective use of physostigmine in reversing 50 cases of GHB overdose [88]. However, the timing of reversal in all of these studies was widely variable, as was the dosing and frequency of physostigmine administration. Given that GHB-induced sedation is almost entirely GABA driven and often rapidly self-terminates, reliable conclusions regarding the role of physostigmine cannot be made from these uncontrolled studies. A systematic review of the available literature found no convincing evidence of physostigmine's role in managing GHB-induced sedation and coma [89]. Furthermore, a recent double-blind, placebo-controlled rat study performed by Bania et al. demonstrated that not only did physostigmine not reverse GHB-induced sedation in any affected rats, 100% of those treated with typical human-equivalent doses of physostigmine developed muscarinic toxicity and seizures [90]. Therefore, it cannot be concluded that there is any role for physostigmine administration in the reversal of GHB-induced sedation.

Administration

Adult

Physostigmine salicylate is available in 2 mL ampules in a concentration of 1 mg/mL. The solution contains sodium bisulfite 0.1% and benzyl alcohol 2% [38]. In adults, the usual recommended dose is 1–2 mg, given intravenously

or intramuscularly (grade II-3 recommendation). When given intravenously, it should be given at a rate of 1 mg/min. The previous literature recommended repeat dosing in 5–10 min if no response and until the desired clinical response was achieved to a maximum of 2 mg per dose. However, as discussed above, that recent animal studies using radio-labeled physostigmine suggest peak cortical cholinesterase inhibition may not be achieved for 20–30 min after intravenous infusion [43–45]. As such, the 5–10 min re-dosing recommendations are not consistent with the now known time frame for maximal pharmacodynamic response. Waiting 5 min before re-dosing may be insufficient to determine the efficacy of the previous dose and could certainly result in dose stacking, potentially causing cholinergic excess (i.e., bronchorrhea, seizures, etc.) [91]. No prospective human data exist with respect to lengthened dosing intervals.

Pediatric

In children, the manufacturer-recommended physostigmine dose is 0.02 mg/kg intravenously or intramuscularly [38]. When given intravenously, it should be given at a rate of 0.5 mg/min (grade III recommendation). Historical recommendations suggest that the dose may be repeated in 5–10 min until the desired clinical response is achieved or adverse effects are seen. However, the same caveats with respect to dosing interval described for adults above also apply in children. Note that if physostigmine is administered intramuscularly, peak absorption may not occur for 23–30 min [40, 42].

Dosing Regimens

Because physostigmine is relatively short-acting, repeat dosing in 30–120 min may be required. When the desired clinical response is achieved, intermittent doses may be used to maintain clinical status. In 45 cases of anticholinergic poisoning treated with physostigmine, central anticholinergic symptoms recurred in 32 (78%) of cases, with

26 cases requiring multiple doses [50]. Oral, subcutaneous, transdermal, and nebulized dosing schemes have been reported for physostigmine administration, but these modalities have not been studied in the management of acute anticholinergic overdose.

The treatment protocol reported by Burns et al. begins with treatment of anticholinergic delirium with 1–2 mg of physostigmine, given by slow IV push over 5 min. Repeat dosing, though performed only 5 min after initial dose, was initiated at 0.5 mg, until resolution of delirium or signs of mild cholinergic excess were observed. With this protocol, 11% of patients developed mild cholinergic symptoms, though none developed seizures. The mean response time was 11 ± 5 min, with a mean duration of effect of 100 ± 42 min [50]. Dawson et al. summarized two different approaches to the amount of physostigmine administered in the initial dose and subsequent re-dosing and found equivalent outcomes despite one protocol utilizing 50% less physostigmine at the same dosing intervals [91]. This suggests that a similar time to response but at a much lower mean dose (2.2 vs. 1.3 mg physostigmine) titration may further support the notion that a 5 min re-dosing schedule may allow insufficient time to determine the efficacy of the previous dose.

In appropriate situations, very large cumulative doses of physostigmine appear to be safe and effective. Several cases have been reported in which large doses of physostigmine were administered over the course of many hours with excellent tolerance, though often in the absence of rational indication for its use. In one case, a 7-year-old girl who had ingested imipramine received 260 mg of physostigmine over 30 h to maintain arousal [92]. In another case, a 55-year-old woman who had ingested a large amount of amitriptyline received 196 mg of physostigmine over 36 h due to persistent sedation is reported [93]. Because this patient did not receive her first dose of physostigmine until 64 h post ingestion, it is questionable whether central anticholinergic toxicity was causing her sedation at that point. Finally, in 1975, a 27-year-old woman who had ingested 9850 mg of a TCA received 74 mg of

physostigmine (in 5–10 mg doses) over 6 h for recurrent ventricular tachycardia without adverse effects, despite there being no rational reason to administer physostigmine for this indication [84].

Successful and uncomplicated use of continuous physostigmine infusions has also been reported. In one case, marked olanzapine-induced anticholinergic delirium in a 6-year-old boy was successfully managed with a physostigmine infusion of 0.5 mg/h (0.167 mg/kg/h) over 16 h [94]. Similarly, a 13-year-old female with recurrent antimuscarinic delirium from a mixed drug ingestion was successfully managed with a physostigmine infusion of 2 mg/h over 8 h without adverse effects [95]. Finally, a 20-year-old female with antimuscarinic delirium from a mixed benztropine and amitriptyline overdose was safely managed with a physostigmine infusion over 8 h with additional boluses over the next 52 h (77 mg physostigmine total), again without apparent adverse effects [96]. There are no controlled experimental data with respect to continuous physostigmine infusion.

Summary

Physostigmine is the ideal antidotal agent for management of antimuscarinic delirium resulting from overdose of pure anticholinergic agents. When titrated appropriately, it can rapidly reverse agitation, reduce hemodynamically significant tachycardia and hyperthermia, and avoid the risks of excessive sedation, prolonged recovery, and emergent intubation when compared to other sedative agents. The complexities of TCA toxicity limit the utility of physostigmine in this setting, and its use is contraindicated in the setting of marked TCA-induced cardiotoxicity with signs of extreme sodium channel blockade. The use of physostigmine is probably best avoided in the management of overdoses associated with seizures. Careful titration is the key to management as cholinergic toxicity can result from rapid physostigmine administration (either in initial infusion or repeat dosing frequency). Appropriate use of physostigmine affords excellent patient benefit with low risk.

Introduction

Prussian blue (PB) is an antidote used to treat patients with confirmed or suspected internal contamination with radioactive cesium (^{137}Cs), radioactive thallium (^{201}Tl), or nonradioactive thallium [1]. It has a molecular weight of 859.3 g/mol and an empirical formula of $\text{Fe}_4^{\text{III}} [\text{Fe}^{\text{II}}(\text{CN})_6]_3$. Two forms of PB exist: insoluble or ferric (III) hexacyanoferrate (II) and soluble or potassium ferric (III) hexacyanoferrate (II) [2]. In the USA, since October 2003, the Food and Drug Administration only approves the insoluble PB as a therapeutic agent (Fig. 1). For this reason, all subsequent references to “PB” in this chapter refer to the insoluble form. PB was introduced as an antidote in the USA for drug preparedness over concerns of the possibility of bioterrorism (e.g., radiologic dispersing device or “dirty bomb”) and other radiation event [3].

The latest report (no. 161, 2009) of the US National Council on Radiation Protection and Measurements states that PB is the preferred decorporation therapy for the radionuclides cesium, thallium, and rubidium (Grade III recommendation) [4]. However, PB is not FDA approved for rubidium.

In 2009, the *Expert Consensus Guidelines for Stocking of Antidotes in Hospitals That Provide Emergency Care* could not reach consensus regarding the stocking requirement for PB [5]. Thus, the majority of hospitals likely do not stock this antidote. Other authors suggest that

Fig. 1 Insoluble PB

hospitals should be prepared for chemical and radiological disasters and that most of them should stock at least 12 capsules of PB 500 mg (Grade III recommendation) [6]. However, in the USA, or its territories, in the event of a national emergency, PB is available through the Strategic National Stockpile [7].

Thallium

There are no human controlled studies on the use of PB as an antidote. The majority of available clinical data on the treatment of thallium poisoning or exposure with PB are derived from case reports [8–28]. These reports all describe cases of nonradioactive thallium ingestion.

Cesium

The majority of human data on the use of PB as an antidote for radioactive cesium are from observational prospective studies [29–32]. Radioactive cesium contamination incidents occurred in April 1986 in Chernobyl (Russia) [32] and in September 1987 in Goiânia (Brazil) [29–31]. Three of the 15 (20%) contaminated subjects in the Chernobyl incident received PB. In contrast, 46 out of the 90 (50%) contaminated subjects from the Goiânia incident were treated with PB, 13 of which were children. Goiânia victims were treated with a substantial delay of at least a week from the initial exposure.

Unfortunately, these articles do not report sufficient detail about the untreated patients to allow a meaningful appraisal of the clinical benefit of this therapy. Case reports of patients with nonradioactive cesium poisoning treated with PB demonstrated a reduction in apparent half-life by more than 50% [33, 34].

Treatment with PB is presumed to be more efficacious if administered as soon as possible after incorporation (Grade III recommendation). It may be difficult to obtain serum thallium or cesium concentrations in a clinically meaningful timeframe. Thus, most of the time the clinician has to resort to qualitative assessment of the likelihood of internal contamination to initiate treatment, especially in disaster situations where individuals closest to the source and those not wearing protective equipment have a highest risk of internal contamination.

Pharmacodynamics

PB is an ion exchanger [35]. It binds with high affinity to cesium and thallium isotopes that have been ingested or inhaled and are excreted in bile [35]. It acts by reducing both the primary uptake and then the gastrointestinal reabsorption of the toxic elements. In vitro studies show that binding of cesium or thallium by PB was maximal at pH 7.5 and decreased at lower pH [36–38]. Theoretically, PB is expected to reach its maximum efficiency when present in the small bowel.

PB acts by reducing the biological half-life of thallium and cesium respectively from about 8 days to 3 days and from about 110 days to 30 days. It also reduces the whole-body effective half-life of ^{137}Cs by 46% in adolescents and by 43% in children from 4 to 12 years of age [29].

The maximal absorptive capacity in vitro for various formulations of PB varies from 59 to 72 mg of thallium/g of PB [39, 40].

Pharmacokinetics

Absorption: PB is not significantly absorbed through intact gastrointestinal wall [35]. However, prolonged treatment in some patients who

received soluble PB resulted in benign and transient blue discoloration of their sweat and their tears, which is suggestive of a small amount of systemic absorption [41].

Distribution and metabolism: As most of the PB is not absorbed via the gastrointestinal system, distribution and metabolism are negligible, if not irrelevant.

Elimination: PB is eliminated unchanged in feces, thus its clearance is proportional to the gastrointestinal tract transit time [35].

Contraindications

According to the manufacturer, no identified contraindications to the use of PB exist [35]. It is generally well tolerated and is considered nontoxic, despite having a nitrile (cyano) moiety [42–44]. However, PB should be used with caution in patients with a history of gastrointestinal obstruction, peptic ulcer disease, preexisting cardiac arrhythmias, or electrolyte imbalances (Grade III recommendation) [4].

Adverse Effects

Constipation and asymptomatic hypokalemia are the most commonly cited adverse effects reported by humans taking therapeutic doses of PB [29, 45]. Toxicity from cyanide release seems to be minimal as reported in a simulated experimental study [46]. In another report of three volunteers each given 500 mg of PB, only 2 mg of radio-labelled cyanide was absorbed, which is negligible [42].

Special Populations

The FDA lists PB as pregnancy category C (teratogenic effects demonstrated in animals but not in humans) [35]. However, the risk of poisoning with thallium or cesium and the lack of systemic absorption of PB mandate an individual risk analysis evaluation [47].

Treatment

Given the delay in obtaining thallium and cesium concentrations, PB therapy must be initiated without laboratory confirmation when internal contamination with either cesium or thallium is suspected (Grade III recommendation).

The dose and schedule for PB has not been established with clinical trials. A volunteer study of two patients given PB for decorporation of radioactive thallium showed a dose-dependent relationship for thallium absorption and maximal absorption 1 h after administration. Thus, divided dosing is recommended [48].

For thallium poisoning, the dose used in clinical reports is 150–250 mg/kg/day divided in three or four doses (Grade III recommendation) [9]. For cesium poisoning, the dose recommended by the manufacturer is 9 g per day in three divided doses [35]. The FDA-approved dosing for PB for children from 2 to 12 years of age is 1 g taken orally three times daily (Grade III recommendation) [35]. The dosing for adolescents over 12 years old and adults is 3 g taken orally three times daily (Grade III recommendation) [35]. Doses may be reduced to 1 or 2 g three times daily when internal radiation levels have substantially decreased or for gastrointestinal intolerance (Grade III recommendation) [35].

The duration of treatment with PB should take into account the amount of contamination (whole-body counting) and the symptomatology and thus essentially rests on clinical assessment [35]. Expert advice can be sought. Radiation measurements, e.g., on a Geiger-Müller counter, should be done regularly to evaluate the degree of residual external contamination (Grade III recommendation) [4]. Radiobioassays should be done to evaluate internal contamination; however, the technology and expertise to measure fecal concentrations of thallium or cesium is unlikely to be available in medical facilities [4]. Arrangements with a designated laboratory should be considered [4]. Stool samples (total voidings) and 24-h urine collections to measure metal concentration prior to the beginning of the treatment and weekly afterwards are recommended to determine the rate of extraction of cesium or thallium,

but this might require sending specimens to a specialized laboratory [4]. Serum electrolytes, complete blood count, renal, and hepatic functions should be assessed prior to administration of PB and monitored weekly during treatment (Grade III recommendation) [35]. For nonradioactive thallium internal contamination, PB should be continued until a 24-h urine specimen results a thallium concentration below 5 mcg/L or until the patient is asymptomatic (Grade III recommendation) [35]. For radioactive thallium or cesium internal contamination, PB should be continued until radiation measurements are lower than the detectable threshold [35]. Therefore, it can be expected that treatment with PB may last more than 30 days.

Dosing of PB in infants and neonates has not been established and is not FDA approved. However, in 2011, the US Biomedical Advanced Research and Development Authority awarded a grant to a PB manufacturer to develop a safe and effective pediatric formulation [49]. At the Public Meeting of the US National Advisory Committee on Children and Disasters on August 8th, 2014, it was mentioned that there have been advances in the research of delivery formulations of PB and it appears some of them may have increased absorptive capacity to cesium over previous formulations [50].

Administration

PB is supplied as 0.5 g gelatin capsules for oral administration [35]. The capsules should be taken with food to stimulate the excretion of cesium or thallium (Grade III recommendation) [35]. In patients who cannot swallow a large quantity, capsules may be opened and mixed with bland or liquid food (Grade III recommendation) [35]. However, this can cause blue discoloration of the mouth and teeth [35]. In critically ill patients who cannot swallow the capsules (e.g., intubated patients), these may be opened and administered by orogastric or nasogastric tube (Grade III recommendation) [9, 15, 18, 19, 27].

Coadministration with a stool softener or mild laxative is suggested as constipation has been reported as the most frequent adverse effect following the use of PB (Grade III recommendation) [4, 29]. This adverse effect may be problematic, as constipation will decrease the fecal excretion of cesium or thallium. PB dissolved in 50 ml of 15–20% mannitol prior to administration is often reported in cases of nonradioactive thallium poisoning (Grade III recommendation) [8, 18, 19, 25, 28].

Pyridoxine (Fig. 1) and the biologically similar compounds pyridoxal and pyridoxamine are as a group commonly known as vitamin B₆. They are found in several dietary sources including nuts, meat, fish, grain cereals, fruits, and vegetables [1]. Pyridoxine is used as an antidote primarily for the control of seizures following poisoning by isoniazid, monomethylhydrazine, *Gyromitra esculenta* mushrooms, and other hydrazines. It may also be useful to reverse the altered mental status associated with these compounds. Pyridoxine hydrochloride is available in both parenteral and oral formulations, is water soluble, and is mostly excreted in the urine. The parenteral formulation has a pH of 2.0–3.8 and can degrade when exposed to light [2].

Pharmacodynamics

The active form of pyridoxine is pyridoxal-5'-phosphate (PLP), which serves a critical role in multiple enzymatic reactions. Importantly, it is a necessary cofactor for the formation of γ -aminobutyric acid (GABA). Isoniazid and other hydrazines inhibit the conversion of pyridoxine to PLP via competitive inhibition of pyridoxine phosphokinase, resulting in decreased GABA, increased glutamic acid, and, subsequently, seizures (see Fig. 2).

Pharmacokinetics

Pyridoxine is absorbed in the jejunum with oral bioavailability ranging from 61% to 81% with a mean of 71% [3]. Time to peak concentration after oral administration is 1.25 h [4]. The conversion of pyridoxine to PLP occurs in the liver, with release of active vitamin into circulating blood. Circulating PLP is bound to serum albumin, and small amounts can be stored in liver and muscle tissue. Of circulating vitamin B₆, 60% is PLP [1]. The half-life of pyridoxine is up to 20 days. The major inactive metabolite 4-pyridoxal acid is excreted in the urine [5]. Biliary excretion accounts for 2% of drug elimination.

Contraindications

The only known contraindication to the use of pyridoxine is known allergy to it or to a component of its preparation.

Adverse Effects

Although generally well tolerated, pyridoxine can be neurotoxic in large doses when used both parenterally and orally. Sensory neuropathy, sometimes delayed, is well reported after long-term, high-dose oral pyridoxine. Case reports of neuropathy have described doses of 2–10 g/day for months and years that have variable levels of improvement. A study of five volunteers treated with 1–3 g/day of pyridoxine showed subjective and electrophysiologic findings consistent with sensory neuropathy within 1.5–7 months of treatment in a dose-dependent fashion [6]. A retrospective series of 16 patients with neuropathy after pyridoxine use showed a possible relationship between dose and duration of use. Those who developed neuropathy after doses of 500 mg/day or less did so after a mean of almost 2 years, while those with doses of 5 g/day or more developed neuropathy after an average of 3 months. Eleven patients had at least some improvement in the months after stopping pyridoxine [7].

Perhaps more relevant to the use of pyridoxine as an antidote are reports of adverse events associated with parenteral administration. Two women who received 2 g/kg IV over 3 days developed severe, debilitating irreversible neuropathy resulting in inability to walk. Also, previously unreported central nervous system symptoms of transient autonomic dysfunction, mild weakness,

Fig. 1 Pyridoxine

Fig. 2 Inhibitory effects of isoniazid on pyridoxine-related metabolic processes

nystagmus, lethargy, and respiratory depression were reported although there was some question as to whether that may have been as a result of the preservative used in the pyridoxine formulation [8]. The toxic dose is not clear; however there have been large doses of parenteral pyridoxine (4–25 g) used in the treatment of isoniazid toxicity without reported adverse event [9].

Pyridoxine may also reduce the effectiveness of levodopa in the treatment of Parkinson's disease via increasing the peripheral decarboxylation of levodopa [10].

Pyridoxine is Food and Drug Category A in pregnancy. There are no studies in the safety of high-dose pyridoxine for INH-induced seizures in pregnant women.

Treatment and Administration

Pyridoxine is indicated for the treatment of isoniazid or other hydrazine-induced seizures (Grade II-3 recommendation). Recommended dose is 1 g of pyridoxine for every gram of isoniazid up to a total of 5 g [9] (Grade II-3 recommendation). A suggested administration for an actively seizing patient is 0.5 g per minute IV until resolution of seizure activity with the remainder given over the next 4–6 h to maintain serum pyridoxine as isoniazid is metabolized [11] (Grade III recommendation). In children, standard recommended dosing is 70 mg/kg, although it has been proposed that a gram-for-gram dosing is indicated for isoniazid poisoning regardless of age [12] (Grade III recommendation). Co-administration of benzodiazepines has a synergistic effect in terminating seizures in animal models [13]. For seizures unresponsive to initial pyridoxine dosing, repeated dosing at 5–20 min intervals until seizure activity terminates has been effective [14] (Grade III recommendation). Pyridoxine may also be considered for persistent coma after isoniazid overdose. In a report of three cases, pyridoxine was used for continued depressed mental status in doses of 3–5 g given up to 42 h after isoniazid ingestion with apparent improvement in mental status [15] (Grade III recommendation). Improvement in depth of coma was also reported in

patients receiving pyridoxine for INH overdose compared to historical controls [9] (Grade II-3 recommendation). Given traditional stocking, a single overdose has the capability of depleting a large region's supply of pyridoxine, so in areas where isoniazid is largely prescribed, collaboration should be preestablished in order to transfer adequate supplies of isoniazid to locations in need [16, 17].

8.4	50	1	2	10

Definitions: *mEq* milliequivalents, *mEq/mL* milliequivalents per milliliters, *mOsm* milliosmols, *mL* milliliters

^aCommonly available sizes

Therapeutic administration of sodium bicarbonate (NaHCO_3) has the ability to alter xenobiotic pharmacokinetic properties, pharmacodynamic profile, or both. Sodium bicarbonate is available generically as 4.2%, 7.5%, and 8.4% intravenous solutions in water. NaHCO_3 is also available as a 500 milliliter (mL) 5% solution and as tablets; however, for purposes of this discussion, only the intravenous solution will be considered. The milliequivalent (mEq) and milliosmolar (mOsm) content of each percentage is included in Table 1 [1]. Due to its decreased osmolality, the 4.2% solution is often preferred for pediatric patients.

The therapeutic effect of sodium bicarbonate as related to different toxins is described below. Due to the inherent lack of controlled trials, all recommendations are based on level III clinical human or animal study evidence unless otherwise specified.

Pharmacodynamics

As a primarily extracellular cation, sodium (Na^+) is a major constituent to ionic balance in the serum. Sodium is also a driving force for the depolarization of cardiac Purkinje fibers responsible for cardiac contraction. Providing additional sodium ions is one mechanism for the therapeutic effects of sodium bicarbonate. Bicarbonate (HCO_3^-) is an extracellular anion and is a major constituent of the ionic and acid–base balance in the serum. Alteration in serum pH has the potential to alter xenobiotic protein and receptor binding, membrane permeation, and volume of distribution. Also, HCO_3^- is excreted by the

kidneys affecting urine pH and, as a result, may alter elimination kinetics of some xenobiotics.

The use of intravenous NaHCO_3 to correct metabolic acidosis is the subject of considerable debate due to concern over increasing arterial carbon dioxide concentrations resulting in intracellular acidosis [2, 3]. This chapter focuses on the use of NaHCO_3 for the treatment of specific xenobiotic exposures and will not address its use for undifferentiated acid–base disorders.

Pharmacokinetics

Once in the serum, sodium bicarbonate dissociates into Na^+ and HCO_3^- ions. The kidneys regulate acid–base balance of serum and urine by the action of the proximal tubules on bicarbonate excretion and reabsorption. HCO_3^- exists in an equilibrium in the serum:

HCO_3^- and carbonic acid (H_2CO_3) exist in roughly a 20:1 ratio at physiologic pH (7.4). Dissolved carbon dioxide (CO_2) is excreted through exhalation, highlighting the importance of adequate respiration following administration of NaHCO_3 .

Contraindications

Adverse effects of NaHCO_3 administration are generally related to hypernatremia and excessive alkalemia. No true absolute contraindications exist for the use of NaHCO_3 during the management of life-threatening drug toxicity. However, cautious use is advised in patients with volume overload, pre-existing alkalemia, or electrolyte and/or mineral imbalance. Bicarbonate causes the intracellular shift of both potassium and calcium, thereby lowering values of measured extracellular serum potassium and calcium without affecting whole-body stores.

Treatment

Sodium Bicarbonate for the Treatment of Sodium Channel Antagonist Toxicity

In the 1950s, reports of reversing cardiotoxicity (i.e., QRS prolongation, hypotension, and cardiac dysrhythmias) caused by quinidine and procainamide toxicity with the administration of sodium lactate were published [4–8]. The use of sodium lactate and sodium bicarbonate for the treatment of tricyclic antidepressant (TCA) cardiotoxicity was introduced shortly thereafter [9–12]. With successful treatment of quinidine and TCA toxicity, use of sodium bicarbonate spread to other agents with similar sodium channel-blocking effects.

Cardiotoxicity from myocardial sodium channel antagonists can be life-threatening, and NaHCO_3 is the treatment of choice for sodium-channel blockade-associated wide complex tachycardia. Rapid influx of sodium during phase 0 of depolarization is responsible for upstroke velocity and V_{max} of the myocytes. Blockade of fast sodium channels impairs depolarization, alters

myocardial function, and predisposes the heart to ventricular dysrhythmias. Altered depolarization is predictably heralded by characteristic electrocardiographic (ECG) changes including QRS widening, right axis deviation, including an R-wave in aVR, and, occasionally, a Brugada-like pattern in the chest leads [13–16]. An ECG demonstrating a wide-complex rhythm following TCA intoxication is shown in Fig. 1.

Electrocardiographic findings are similar among sodium channel antagonists (namely, QRS prolongation). Administration of NaHCO_3 boluses is considered the mainstay of therapy for poisoning by drugs causing sodium channel blockade with evidence of response across many pharmacologic classes (Level of Evidence (LoE) III). Adjunct therapies may be beneficial in some cases, but even though these therapies are being used in conjunction, they should be thought of separately with NaHCO_3 targeting the signs of cardiotoxicity. The benefits of NaHCO_3 administration in the treatment of sodium channel antagonist toxicity are likely multifactorial. The presence of an excess of sodium ions promotes sodium influx.

Fig. 1 Demonstration of TCA toxicity (Reprinted with permission: <http://lifeinthefastlane.com/ecg-library/basics/tca-overdose/>)

Alkalinization of the serum and receptor may decrease receptor binding, increase protein binding (making less drug available at the receptor), and promote change in ionized fraction of the drug, especially for acidic drugs. The comparative effects of sodium alone (3% sodium chloride (NaCl)), alkalemia alone, and combined sodium and alkalemia (NaHCO_3) have been evaluated in both in vitro and in vivo animal models [15, 17–20]. No true single benefit has been defined and the results vary depending on toxin. However, the use of NaHCO_3 has shown similar or improved benefit compared to hypertonic sodium chloride while alkalemia alone was the least beneficial amongst the treatments studied [15, 17–20]. Of note, the animals treated with sodium chloride received the equivalent of 15 mEq/kg sodium which is clinically unrealistic. In the case reports, retrospective reviews, and animal studies showing effective treatment, NaHCO_3 was administered as a bolus.

Important considerations when giving NaHCO_3 for sodium channel blockade include the following: (1) studies and case reports showing therapeutic effect from NaHCO_3 were done using bolus administration. Bolus dosing allows for administration of 50 mEq of NaHCO_3 in 5–10 min depending on catheter size, as opposed to an infusion such as the administration of 150 mEq with 850 mL of 5% dextrose in water (D5W) administered at 250 mL/h, in which case only 37.5 mEq NaHCO_3 will be delivered per hour. (2) Following the NaHCO_3 bolus, ECG monitoring is necessary to observe for response to therapy and the need to administer additional doses. (3) NaHCO_3 boluses may need to be repeated to an end point of dysrhythmia cessation or a significant decrease in QRS duration (generally <120 msec). Repeat bolus doses of NaHCO_3 may also be required if the QRS again widens. Serum sodium concentration and acid–base status should be monitored and, in general, NaHCO_3 therapy is discontinued if serum pH exceeds 7.55 or serum sodium concentration exceeds 155 mEq/L. Medications known or believed to cause sodium channel blockade through mechanism of action or similarity to other agents are reported in Table 2.

Antidepressants

Sodium bicarbonate use for antidepressant toxicity, especially TCAs, has provided critical evidence for its effectiveness. As quinidine and procainamide provided an introduction to the use of NaHCO_3 during toxicity, research into TCA toxicity has provided guidelines for its effective use and dosing recommendations for managing toxicity of other cardiac sodium channel antagonists. In TCA overdose, hypotension, QRS prolongation, and tachydysrhythmias often occur. Significant TCA overdoses are frequently associated with an awake and mildly sedated patient, followed by a precipitous, and sometimes catastrophic, decline in both neurologic and cardiovascular status. The first few hours after overdose are critical for observation of symptom onset. Successful use of NaHCO_3 for the reversal of TCA-induced QRS prolongation and dysrhythmias has been reported in both adult and pediatric patients [11, 20–29].

During investigation for a dose–response effect in amitriptyline toxicity, a landmark paper reported the observation of a greater correlation between QRS duration for the development of seizures and ventricular dysrhythmias, than was seen with serum amitriptyline levels [13]. In this study population, 34% of patients with a QRS duration ≥ 100 msec experienced seizure activity and 50% of patients with a QRS duration ≥ 160 msec developed ventricular dysrhythmias. The presence of right-axis deviation in aVR has also been used as a prognostic indicator in TCA toxicity. In patients with an R-wave of at least 3 mm aVR, 43% developed seizures or dysrhythmia while 80% of those with an R-wave of at least 5 mm had seizures or dysrhythmias. The R/S ratio >0.7 was also associated with 46% of patients developing seizures or dysrhythmias [30]. However, not all sodium channel antagonists lead to such observable changes in aVR. Based on these observations, NaHCO_3 bolus therapy is recommended for a QRS ≥ 160 msec (LoE III). The indication for NaHCO_3 in patients with widened QRS between 100 and 160 msec is based on the combination of QRS duration and clinical manifestations such as hypotension, potential degeneration to ventricular tachycardia or ventricular fibrillation, acidemia, or seizures (LoE III).

The use of NaHCO_3 may also be reasonably considered if progressive QRS widening >100 – 140 msec is evident (LoE III).

Selective serotonin reuptake inhibitors (SSRIs) are generally much less cardiotoxic in overdose than TCAs. However, citalopram and its S-enantiomer, escitalopram, have been associated with reports of delayed onset seizures and cardiac dysrhythmias [31–34]. Case reports demonstrate adult and pediatric patients presenting with prolonged QRS intervals following citalopram or escitalopram overdose which were responsive to NaHCO_3 boluses [31–34]. Although QT_c prolongation with a normal QRS interval is the more commonly reported ECG abnormality associated with citalopram or escitalopram overdose, the use of NaHCO_3 should be considered for patients presenting with a widened QRS or ventricular dysrhythmias. Overdose of venlafaxine, a serotonin and norepinephrine reuptake inhibitor, may also result in sodium channel blockade with reported response to treatment with NaHCO_3 [35, 36].

Bupropion, an aminoketone antidepressant, has been associated with QRS prolongation and ventricular dysrhythmias in overdose [37–39]. Case reports describe both success and failure of NaHCO_3 for the treatment of QRS widening and dysrhythmias [38, 40]. One case describes failure of response to the NaHCO_3 while the other reports initial response and placement on a continuous infusion with later decompensation, highlighting the potential need for the higher doses of NaHCO_3 achieved with bolus administration compared to a continuous infusion [37, 39]. Animal data suggest bupropion toxicity may involve a mechanism other than sodium channel blockade, possibly also explaining the apparent lack of response to NaHCO_3 [40]. However, given bupropion's similar presentation to classic sodium channel antagonist toxicity, and the relatively low risk associated with sodium bicarbonate therapy, NaHCO_3 is considered an appropriate initial treatment for bupropion-induced cardiotoxicity (LoE III).

Neuroleptics

Thioridazine and its metabolite, mesoridazine, are phenothiazine neuroleptic agents. The

predominant therapeutic activity of thioridazine is due to dopamine inhibition, but sodium channel-related cardiotoxicity may occur during therapy or following overdose [41, 42]. In a prospective, observational study conducted between January 1987 and January 1994, cardiotoxicity from thioridazine was more commonly observed than with any other neuroleptic agent in use during the study period and was often delayed [41]. Given the similarity to other QRS prolonging agents, treatment with NaHCO_3 boluses is appropriate for thioridazine- and mesoridazine-induced cardiotoxicity (LoE III).

Antiepileptics

Lamotrigine is an antiepileptic medication that inhibits propagation of seizure activity from epileptic foci. In overdose, QRS prolongation leading to dysrhythmias and heart block suggestive of myocardial sodium channel antagonism have been reported [43–46]. Success and failure of NaHCO_3 therapy for lamotrigine-induced cardiotoxicity have both been reported [42–45]. However, it is noteworthy that the amount of NaHCO_3 administered is unclear and under-treatment may have contributed to reported failure [43]. Therefore, treatment with NaHCO_3 may be attempted for lamotrigine-related cardiotoxicity, but adjunct measures may be required in a severely poisoned, unstable patients or those unresponsive to ample (2–3 mEq/kg) bolus doses of NaHCO_3 (LoE III).

Antihistamines

Overdose with first-generation antihistamines such as diphenhydramine, doxylamine, and chlorpheniramine may result in myocardial sodium channel toxicity [47–52]. Diphenhydramine cardiotoxicity has been reported to respond to varying doses of NaHCO_3 from 44 to 200 mEq (4.3 mEq/kg) [47, 50]. Given the ECG findings and reported response, NaHCO_3 is recommended in patients exhibiting cardiotoxicity from first-generation antihistamines (LoE III).

Propoxyphene

Propoxyphene is a μ -opioid receptor agonist paired with other analgesics (e.g., acetaminophen)

for management of acute pain. Treatment of propoxyphene-induced QRS prolongation with NaHCO_3 has been reported [53]. Due to its toxicity and lack of robust analgesic data, the US Food and Drug Administration (FDA) recommended voluntary withdrawal of propoxyphene from the US market in 2010 [54]. Analogous agencies in several other countries have taken similar actions. In 2013 and 2014, 28 and 19 cases of exposure to propoxyphene were reported to US poison centers, respectively, demonstrating continued persistence of this drug even without continued prescribing in the US [55, 56]. Propoxyphene may still be available in some countries.

Anti-infectives and Rheumatologic Agents

Cardiotoxicity from the antimalarial and anti-inflammatory drugs, chloroquine and hydroxychloroquine, includes QRS prolongation and ventricular dysrhythmias. The use of NaHCO_3 has been effective in decreasing QRS duration and may be used in conjunction with electrolyte replacement, epinephrine, and high-dose diazepam [57–61]. These agents have also been associated with significant hypokalemia. Serum potassium concentrations must be monitored closely during alkalinization treatment as the intracellular shift of potassium from the alkalinization may compound the hypokalemia from the ingestion.

Quinine has several medical and nonmedical uses, including an antimalarial agent, abortifacient, treatment of leg cramps, and recreational drug adulterant. Quinine is a quinidine stereoisomer and quinine-induced QRS prolongation predictably responds to NaHCO_3 boluses [62]. These agents are discussed in greater detail in ► Chap. 64, “Chloroquine and Quinine.”

Cocaine

Cocaine is a stimulant derived from coca leaves and acts by increasing the concentration of norepinephrine, epinephrine, and dopamine in the synaptic cleft. Additionally, cocaine acts as a local anesthetic and has sodium channel antagonist properties. Cardiotoxicity from cocaine may include tachycardia or bradycardia, chest pain,

palpitations, QRS prolongation, and ventricular tachycardia as well as signs of vasospasm. Reversal of QRS prolongation and resolution of dysrhythmias has been reported in humans and animals [63–71]. NaHCO_3 is recommended in the treatment of cocaine-related cardiotoxicity (LoE III). One case in a series describing patients presenting with cocaine intoxication was treated with NaHCO_3 with resulting improvement in the QRS duration and right-axis deviation in aVR [64]. The responsiveness of cocaine-associated QRS widening to NaHCO_3 administration has been further supported through case reports and animal studies and it is considered first-line treatment (LoE III) [64–70]. Other therapies for cocaine toxicity are discussed in greater detail in ► Chap. 75, “Cocaine.”

Antidysrhythmics

Vaughan Williams Class I antidysrhythmic agents are classified based on their antagonist effect and duration of activity at the cardiac sodium channels. These agents also have varied effects on the potassium rectifier channels. Excess effect predictably causes classic sodium channel antagonist cardiotoxicity. That being said, the three subclasses of Vaughan Williams Class I antidysrhythmics vary in their effect on sodium channel, especially the duration of channel blockade, as demonstrated in Fig. 2.

Class Ia agents include disopyramide, procainamide, and quinidine. Much of the current understanding of sodium channel toxicity and bicarbonate therapy is derived from experience with quinidine and procainamide. These agents block both sodium channels and potassium rectifier channels resulting in prolonged QRS and QT_c

intervals. Class Ia agents have a varying effect on cardiac sodium channels with time to recovery of 9, 18, and 3 seconds (s) for disopyramide, procainamide, and quinidine, respectively [72]. The majority of published human and animal experience in treating quinidine and procainamide cardiotoxicity is with sodium lactate [4–8]. However, due to lack of easily accessible sodium lactate and apparent similar effect, NaHCO_3 is considered the agent of choice in the treatment of QRS prolongation and dysrhythmias from these agents (LoE III).

Class Ib agents have the least impact on the upstroke velocity of the Class I agents and generally have very little, if any, effect on potassium rectifier channels. As such, these agents exert the greatest effect on conduction, and not repolarization, of the heart. Of the antidysrhythmic agents affecting sodium channels, lidocaine has the shortest blockade at 0.1 s [72]. With this “fast on, fast off” property, lidocaine has been employed in the treatment of sodium channel blockade refractory to NaHCO_3 and other treatments due to its ability to competitively inhibit the receptor while allowing for a rapid return of the receptor to its natural state. Other class Ib agents include mexiletine, phenytoin, and tocainide. These agents are also associated with rapid sodium channel recovery of 0.3, 0.2, and 0.4 s for mexiletine, phenytoin, and tocainide, respectively [72]. Cardiovascular collapse associated with intravenous phenytoin administration is proposed to be due to the propylene glycol diluent and is presumed unrelated to phenytoin itself. Outside of lidocaine, Class Ib agents have not been effectively employed in the treatment of patients with cardiac sodium channel blockade.

Fig. 2 Class I antiarrhythmic drug effects (Reprinted with permission from: <http://tmedweb.tulane.edu/pharmwiki/lib/exe/fetch.php/classI.png>)

Vaughan Williams Class Ic agents have the greatest impact on the upstroke velocity and are often difficult to treat in overdose. Reported recovery times for blocked sodium channels are 11, 10, and 1 s for flecainide, moricizine, and propafenone, respectively [72]. Cardiac effects in toxicity include bradycardia, tachycardia, QRS prolongation, and ventricular tachycardia with arrest [73]. Given their influence on several cardiac receptors (which may include influences on intracellular calcium), duration of action at the receptor, and varying pharmacokinetic profiles, toxicity from these agents can be difficult to treat [18, 73–76]. The ability of NaHCO_3 to reverse cardiotoxicity from flecainide, encainide, and propafenone has been demonstrated in neonates, pediatrics, adults, and in animal models. NaHCO_3 is recommended for all patients with QRS prolongation or dysrhythmias from Class Ic drugs (LoE III) [73, 77–88].

For patients with toxicity from Class I antidysrhythmic agents that present with a prolonged QRS, sodium channel antagonism is likely. If the patient is experiencing a significantly prolonged QRS interval, administration of IV bolus NaHCO_3 with a repeat ECG and repeated dosing when necessary is appropriate (LoE III). As these intoxications can be difficult to treat, additional therapies may be required.

Beta Adrenergic Receptor Antagonists

In a prospective, poison center-based study, ECGs in patients with reported overdoses including beta antagonists were collected and evaluated. In the 17 patients with ECG changes, acebutolol, labetalol, and propranolol appeared to have the greatest effect on QRS duration, suggesting cardiac sodium channel blockade occurred [89]. Prolongation of the QRS interval has been observed in a case of propranolol overdose [90]. Animal studies of propranolol toxicity using isolated heart preparations suggest that increased sodium may increase contractility and augment other therapies [91]. In patients with QRS prolongation after ingestion of beta-antagonists, including NaHCO_3 with other treatment modalities discussed in the beta-antagonist chapter is appropriate (LoE III).

Fig. 3 Figure A is from a normal patient and Figure B is from a patient with Brugada syndrome (Figure courtesy of Dr. J Heuser under a Creative Commons license)

Brugada syndrome is described as a triad of clinical and ECG findings characterized by Martini and Brugada in the 1980s and 1990s [92, 93]. These characteristics include (Fig. 3):

1. ST-segment elevation (permanent or transient) in V_1 – V_3
2. Presence of a right bundle branch block (RBBB) in the precordial leads (may be absent in 1/3 of patients)
3. Sudden cardiac death

These patients often have no signs or symptoms of cardiac disease [93, 94]. Brugada syndrome may be related to mutations in the cardiac sodium channel and is treated with the implantation of a cardioverter-defibrillator. Electrocardiograph changes including permanent or transient ST-segment elevation in V_1 – V_3 (with or without RBBB in the precordial leads (“Brugada sign”)) have also been associated with right ventricular pathology, electrolyte abnormalities, and exposure to xenobiotics. Sodium channel antagonists have also been reported to uncover latent Brugada

syndrome, leading to reports of a drug-induced Brugada sign [94, 101]. Brugada sign has been reported in multiple sodium channel blocking agents including TCAs, cocaine, Class Ia and Ic antidysrhythmic agents, propranolol, venlafaxine, and propoxyphene [25–28, 67, 92–101]. NaHCO_3 has occasionally been successful in reversing drug-induced Brugada sign [25–29, 31–39, 67]. Due to the occasionally evolving or transient nature of the syndrome, determining the role of the agent in causing versus unmasking Brugada sign is difficult. ECG findings due to genetic sodium channel defects and drug-induced sodium channel blockade are indistinguishable. Therefore, in the face of potential drug toxicity, patients with Brugada sign ECGs are candidates for NaHCO_3 bolus therapy (LoE III).

This topic is discussed in greater detail in ► Chap. 39, “Sodium Channel-Blocking Antidysrhythmics.”

Based on the above, the author recommends the following in patients with a known or suspected toxicity from a sodium channel antagonist:

1. Patients with a new QRS duration ≥ 100 msec, a terminal R-wave in aVR ≥ 3 mm, or an R/S ratio in aVR ≥ 0.7 be closely monitored for progression of clinical effects (LoE III).
2. Sodium bicarbonate bolus beginning at 2–3 mEq/kg is the first-line treatment for a wide-complex dysrhythmia (e.g., ventricular tachycardia) with repeat dosing as needed (LoE III).
3. Patients with a QRS ≥ 160 msec represent the highest risk of developing ventricular dysrhythmias and NaHCO_3 administration (2–3 mEq/kg) is appropriate (LoE III).
4. Sodium bicarbonate administration in patients with a QRS ≥ 100 msec when other major manifestations consistent with sodium channel toxicity are present is reasonable (LoE III).
5. Endpoint of NaHCO_3 therapy is the cessation of ventricular dysrhythmia, significant narrowing of the QRS duration, serum pH > 7.5 , or sodium > 155 mEq/L. Except in cases of significant alkalemia or hypernatremia, sodium bicarbonate boluses can be repeated (LoE III).

Sodium Bicarbonate to Enhance Urinary Elimination of Xenobiotics

In addition to treating xenobiotic-related sodium channel antagonism, sodium bicarbonate is also employed therapeutically to enhance urinary elimination of acidic compounds. Xenobiotics exist in the human body in a balance of ionized and nonionized forms. The acid dissociation constant (pKa) is defined as the environmental pH at which the compound will exist in a 50% ionized state. Since pKa is a logarithmic function, a small change in blood pH can lead to substantial changes in the ionized fraction of a compound. For a weak acid such as salicylic acid, as serum pH decreases, the fraction of nonionized drug, which readily crosses membranes, increases. As a result, penetration into the central nervous system (CNS) increases. In contrast, increasing the pH causes the ionization equilibrium to shift in favor of the ionized fraction of acidic xenobiotics. When ionized (i.e., charged), less of the compound is able to freely cross membranes, including in the blood–brain barrier and renal cells. When the urine is alkaline, the higher pH causes the ionized xenobiotic to become “trapped” in the urine and subsequently leads to a reduction in reabsorption and greater excretion, and greater excretion. Although urine pH and “ion trapping” of xenobiotics in the urine are the focus of this discussion, the rise of the serum pH and prevention of penetration into other compartments (e.g., the CNS) follow a similar principle.

Historically, urinary alkalization for enhanced elimination was coupled with forced diuresis. However, forced diuresis does not generally result in enhanced xenobiotic elimination and is no longer recommended [102]. For toxins responsive to therapeutic urinary alkalization, increased excretion is achieved without the requirement of specialized equipment or invasive measures and may be used independent of hemodialysis in patients with adequate renal function. Alkaline therapy can also serve as a bridge when hemodialysis is not emergently available. To be effective, adequate renal perfusion and kidney function are imperative. In addition to the renal function and pKa of the toxin, effective treatment

with urinary alkalization is also dependent on the extent of urinary excretion of the active compound and the urine pH. For example, if 5% of the dose is excreted in its unchanged form, doubling and even tripling that rate will not appreciably change overall elimination rate to a clinically meaningful degree. Urinary alkalization as a treatment modality has been proposed in salicylate, barbiturate, methotrexate, chlorophenoxy herbicide, fluoride, and chlorpropamide toxicity [102]. Fluoride and chlorpropamide will not be discussed, as this intervention is not likely appropriate for toxicity caused by these agents. Patients should be evaluated for appropriateness of alkalization therapy based on serum drug concentration (e.g., plasma salicylate) when available and clinical manifestations of toxicity. Underlying disease states that may limit tolerability of large fluid load or impaired excretion of the drug (e.g., the presence of cerebral or pulmonary edema or liver, heart, or renal failure) must be considered.

No fully evidence-based protocol for achieving urine alkalization with NaHCO_3 is available. However, the components of urine alkalization include initial bolus administration of NaHCO_3 followed by continuous infusion, monitoring for target urine pH, maintenance of adequate potassium, and monitoring for adverse effects. One expert consensus position paper recommends a NaHCO_3 dose over the first hour of treatment in adults of 225 mmol (mEq) and 25–50 mmol (mEq) for children to promote adequate urinary alkalization [102]. Delivery of the proper dose for an adult can be accomplished through administration of a bolus with 150–200 mEq of 8.4% NaHCO_3 followed by a continuous infusion (LoE III). The infusion is prepared by the addition of 150 mEq of NaHCO_3 (150 mL of 8.4% NaHCO_3 to 850 mL of 5% dextrose in water (D5W), with 20–40 mEq potassium chloride or acetate. The recommended infusion rate is 200–250 mL/h (i.e., double the typical maintenance fluid rate of 100–125 mL/h) (LoE III). D5W is the preferred base solution to limit risk of hypertonic fluid administration and potential hypernatremia (0.9% sodium chloride (NaCl), i.e., “normal saline”, contains 154 mEq/L of sodium). No controlled studies have addressed

the effect of a bolus on achieving goal urine pH; however, in patients receiving only the infusion achievement of goal pH may be prolonged. The NaHCO_3 infusion is then used to maintain a urine pH of 7.5–8. Urine pH should ideally be checked every 15–30 minutes (but no longer than every 60 minutes) until the target pH is achieved and hourly, thereafter. This necessitates foley catheter placement to aid in frequent urine testing. Other laboratory parameters requiring close observation during alkalization therapy include acid–base status (arterial pH <7.50), serum potassium (>4.0 mEq/L), and plasma xenobiotic concentrations, when clinically feasible (LoE III). Once alkalization therapy is initiated, the serum pH must be monitored for development of excessive alkalemia (pH >7.5) that might interfere with oxygen delivery. With this shift, oxygen less readily dissociates from hemoglobin. As such, the serum pH must be evaluated prior to initiating alkalization therapy and monitored closely throughout.

The addition of 40 mEq of potassium to the infusion is recommended (LoE III). Close observation of serum potassium concentration is essential as administration of NaHCO_3 causes potassium to shift from the extracellular to the intracellular space. Additionally, hypokalemia causes the kidneys to retain potassium and excrete a proton (H^+), subsequently preventing effective urine alkalization. Serum potassium concentrations can be expected to fall once adequate NaHCO_3 treatment is initiated. Patients may require significant potassium replacement to maintain the goal serum potassium >4.0 mEq/L and achieving any degree of urinary alkalization is unlikely unless there is concomitant potassium replenishment.

Serum calcium must also be monitored as symptomatic hypocalcemia has also been described in patients receiving NaHCO_3 infusions (LoE III) [102, 103]. Therapeutic alkalization requires significant bedside attention to ensure laboratory assessments are performed and appropriate adjustments are made. Not all patients will clinically require a critical care setting; however, placement on a hospital unit with a lower nurse-to-patient ratio may be necessary to optimize patient care.

Salicylates

In the early twentieth century, patients were observed to tolerate higher salicylate doses without symptoms of toxicity when receiving concurrent alkalinization [103]. In the 1940s, this observation prompted attempts at therapeutic alkalinization for the management of salicylate toxicity and the clinical utility of urinary alkalinization was pursued [104, 105]. A urine pH above 7 was shown to decrease salicylate elimination half-life, increase clearance, and increase the excretion of the parent compound, with variable effects on metabolites in adults and children (LoE III); this has also been reproduced in animal models [105–110]. This increased elimination rate has been reported as much as threefold in one report and was reported to increase from 5.2 to 7.1 mg/kg/h in children [106, 108]. The rate of excretion is affected by three factors: plasma salicylate concentration, rate of urine flow, and pH (specifically, alkalinity) of the urine [107]. Salicylate protein binding is saturable with >95% binding at serum salicylate concentrations up to 20 mg/dL, versus 30–40% total binding with levels greater than 70 mg/dL [107]. This increase in unbound drug allows for greater urinary excretion of the parent compound. With therapeutic alkalinization, patients can manifest a degree of alkalemia (pH > 7.45), though typically with an unappreciable increase in plasma sodium concentration, and a slight decrease in plasma potassium concentration, averaging 1.1 mEq/L [107]. A rat model of salicylate toxicity also demonstrated the addition of NaHCO₃ to correlate with a decrease in salicylate concentrations in muscle, brain, and liver tissue [110].

The pKa of salicylic acid is 3.3. Alterations in the acid–base balance can significantly alter salicylate tissue penetration with an increase in CNS penetration associated with worsening acidemia [110]. Therapeutic alkalinization can serve as a temporizing measure in severe salicylism during preparation or transfer of the patient for emergent hemodialysis. Additionally, therapeutic alkalinization may serve as the primary mode of enhanced elimination in patients with significant, but not immediately life-threatening, salicylate toxicity in whom hemodialysis may not be indicated.

In addition to acid–base status and serum potassium, hydration status impacts alkalinization. Dehydration and subsequent decreased glomerular flow limits the effectiveness of alkaline therapy. Vomiting, diaphoresis, hyperpnea, and tachypnea associated with salicylate toxicity may create significant insensible fluid loss. Therefore, to enhance therapeutic alkalinization, salicylate poisoned patients frequently need fluid resuscitation. Fluid bolus of at least 20–40 mL/kg of 0.9% NaCl for adults with normal renal and cardiac function (20 mL/kg for pediatric patients) is recommended (LoE III). The ideal serum salicylate concentrations to initiate or discontinue therapeutic alkalinization remain unknown. However, given changes in unbound drug and propensity to cause significant symptoms, serum salicylate concentrations greater than 40 mg/dL is a reasonable threshold (LoE III). Therapy may also be initiated in severely symptomatic patients with lower salicylate concentrations but may be less effective as a smaller fraction of free drug is present and the risk may outweigh the potential benefit. Discontinuation of alkalinization therapy should be considered when symptoms resolve and serum salicylate concentrations fall below 30–35 mg/dL in adults or 25 mg/dL in pediatric patients [102]. Salicylate toxicity and its treatment are discussed in greater detail in ► Chap. 63, “Salicylates.”

Phenobarbital

Phenobarbital, a barbiturate sedative-hypnotic GABA_A receptor agonist, has been used for treatment of status epilepticus and alcohol withdrawal in the hospital and seizure prophylaxis in the community. Phenobarbital is also a commonly used veterinary antiepileptic. The half-life of this drug can be extraordinarily long (1.5–4.9 days with therapeutic use) and, with large doses, phenobarbital can exhibit zero-order (saturable) kinetics. Evidence supporting therapeutic alkalinization in the setting of phenobarbital toxicity is mixed. Alkalinization of the urine decreased the half-life of phenobarbital but multidose activated charcoal (MDAC) was superior [102, 111–113]. A recent systematic review concluded that urinary alkalinization was not an effective mode of enhanced elimination of phenobarbital but supports use of MDAC

and hemodialysis or hemofusion [112]. However, the studies comparing MDAC with therapeutic alkalization had several limitations including a lack of urine pH reporting making it unclear if adequate pH was achieved. Given the relatively high pKa of phenobarbital (~7.4), urine pH likely requires a significant increase to clinically change elimination half-life and a lack of alkaline pH may have contributed to the varied results. Given the potential to decrease half-life and little risk of harm, therapeutic alkalization can be employed as an adjunct therapy in phenobarbital toxicity with careful evaluation for goal urine pH (>7.5) (LoE III). All therapies are discussed in greater detail in ► Chap. 46, “Barbiturates.”

Methotrexate

Methotrexate is a folate reductase inhibitor used in the treatment of certain cancers, extrauterine pregnancies, and rheumatologic or other autoimmune disorders such as rheumatoid arthritis and psoriasis. Treatment modalities for toxicity include hydration, folinic acid (leucovorin), and glucarpidase. Dosing recommendations for methotrexate are highly variable ranging from a high-dose administered intravenously over 4 h followed by “leucovorin rescue” to a once weekly oral dose, depending on indication and therapeutic goal. High doses of methotrexate can approach the solubility limit of the drug in the kidneys leading to crystalluria with renal impairment or damage. A NaHCO_3 infusion has been used along with intravenous hydration for renal protection from methotrexate [102, 114–117]. By raising urine pH, the solubility of methotrexate is increased and the fluid assists in dilution. Urinary alkalization can also increase methotrexate excretion rate and decrease elimination half-life [114, 115]. Administration of NaHCO_3 in pediatric patients receiving high-dose methotrexate for acute lymphocytic leukemia was found to be associated with lower 21- and 44-h blood methotrexate concentrations, as well as fewer reports of methotrexate toxicity [116]. Though likely not as effective as hemodialysis, therapeutic alkalization can be considered in patients at risk for methotrexate toxicity (LoE III) [102]. Given potential effects of methotrexate on the kidneys, therapeutic alkalization should be

employed early with close monitoring of urine output. This topic is discussed in greater detail in ► Chap. 60, “Methotrexate.”

Chlorophenoxy Herbicides

Chlorophenoxy compounds, such as 2,4-dichlorophenoxyacetic acid (2,4-D), are widely used herbicides. Though effects from occupational dermal exposure are often limited to local skin irritation, ingestion can lead to significant local and systemic toxicity. In conjunction with volume loading, urinary alkalization has been proposed to increase excretion of chlorophenoxy compounds. Therapeutic benefit is likely due to a combination of alkalization and fluid loading, as the greatest benefit was observed when urine output exceeded 600 mL/h [117]. In the event of ingestion of the chlorophenoxy herbicides, therapeutic alkalization may be considered (LoE III). However, focus should remain on maintaining high urine output (>600 mL/h) (LoE III) [102]. Due to the inability to retrieve levels, discontinuation of therapy should be considered with symptom improvement (LoE III).

Sodium Bicarbonate for the Treatment of Chlorine Gas Inhalation

At room temperature, chlorine exists as a dense, yellow-green gas. Chlorine gas is classified as a pulmonary irritant and exhibits intermediate water solubility. Water solubility is a significant determinant for the time-course between exposure to irritant gases and development of symptoms.

Though once employed as an agent of chemical warfare, present-day chlorine gas exposures are generally from more routine nonwarfare practices such as mixing cleaning chemicals, working with swimming pool chemicals, and in various industrial settings. While most reported cases involve individuals, accidental mass exposure to chlorine has also been reported [118–129]. Adding an acid to sodium hypochlorite (bleach) causes chlorine gas to be released and when ammonia is combined with bleach, chloramine is produced. This circumstance is the cause of many residential chlorine exposures [129]. Swimming pools are chlorinated

for the purpose of disinfection and pH is adjusted using different chlorine-containing products.

Though exposure to pulmonary irritants like chlorine gas is the most common source of toxic inhalants. Specific recommendations for medical management of symptomatic patients has not been well-defined remaining symptomatic and supportive measures (e.g., bronchodilators, humidified oxygen, steroids, and antibiotics when clinically indicated) [125]. The recommendation for use of nebulized, inhaled sodium bicarbonate solutions reportedly originated with Done in a 1976 review of chlorine gas exposure [127, 128]. The postulated benefit of inhaled NaHCO_3 solutions is due to its buffering capacity of the hydrochloric acid (HCl) created by chlorine gas contact with moist mucous membranes [127]. Although chemically this approach is reasonable, most of the HCl has already been neutralized by the membranes when a patient arrives for medical care. If NaHCO_3 aids through buffering the environment, then the benefit to its use should be greatest near the time of exposure. Published cases report symptom improvement following NaHCO_3 even when given several hours after chlorine exposure [119, 123–128].

The available literature on this topic includes one study, retrospective reviews, and case reports [119, 123–128]. In the prospective, double-blind, placebo-controlled study, patients presenting with reactive airways dysfunction syndrome (RADS) following chlorine exposure from April 2004 to April 2005 were included for treatment with intravenous prednisolone (1 mg/kg/day) and salbutamol inhaler (5 mg), plus either nebulized placebo (undefined) or nebulized NaHCO_3 (4 cm³ of 4.20% NaHCO_3 solution). Pulmonary function tests showed an increase in FEV₁ at 120 and 240 min following treatment in the NaHCO_3 group versus placebo. Quality of life scores showed improvement from baseline in both groups with no difference between the treatment groups [124]. In a retrospective poison center review, one patient reportedly experienced immediate relief of symptoms following administration of nebulized NaHCO_3 . However, temporal response was not reported in other patients, and this study did not include control patients

[124]. Another retrospective review described soldiers exposed to chlorine gas in their barracks following improper mixing of cleaning agents. Those patients not responding to initial treatment of bronchodilators and humidified oxygen received NaHCO_3 and an inhaled corticosteroid. In patients presenting with cough and dyspnea, those receiving additional treatment ($n = 15$) did not differ in discharge rate (67% discharged and 33% admitted in both groups) from those receiving no additional treatment ($n = 3$) [118]. Patients with a sore throat and chest pain were included in the review. Two pediatric case reports and one adult case series report rapid improvement in symptoms following the administration of nebulized NaHCO_3 [126–128].

Risk and prognostic indicators for patients for developing delayed pulmonary edema following chlorine gas exposure are not fully defined. As such, it is unclear what, if any, treatment may aid in prevention of this condition. Also, patients with significant chlorine gas exposure may develop chronic pulmonary pathology and the effectiveness of initial treatment strategies at prevention of chronic sequelae is unknown.

In patients with symptomatic upper and lower airway symptoms following chlorine gas exposure, nebulized NaHCO_3 solutions may be considered in addition to other symptomatic treatment measures (LoE I). The solution can be created with the mixture of 3 mL NaHCO_3 with 2 mL of 0.9% NaCl. Other suggested concentrations include: 2 mL 8.4% NaHCO_3 with 2 mL 0.9% NaCl for 4.2% total concentration or 2 mL 7.5% NaHCO_3 with 2 mL 0.9% NaCl.

The treatment of chlorine gas inhalation is discussed in greater detail in ► Chap. 100, “Irritant and Toxic Pulmonary Injuries.”

Sodium Bicarbonate in the Treatment of Methanol Toxicity

Methanol is a toxic alcohol often used in automotive and camping equipment. The parent compound, methanol, may cause mild inebriation but is not associated with significant systemic toxicity. In humans, methanol is metabolized first by

alcohol dehydrogenase (ADH) to formaldehyde which is in turn converted by aldehyde dehydrogenase (ALDH) to formic acid, the entity presumed to be primarily responsible for the toxic effects of methanol exposure. Formic acid accumulates and causes significant anion gap metabolic acidosis. Additionally, formic acid may increase lactate production through inhibition of the mitochondrial cytochrome c oxidase activity. The resulting lactate accumulation may further contribute to the acidosis and acidemia, but formate remains the primary driver of acid–base disturbance and formation of the anion gap [130–132]. Formic acid has a pKa of 3.7 and, at physiologic pH, exists primarily in the de-protonated anionic form known as formate. However, using the Henderson-Hasselbach equation, with a decrease in blood pH of only 0.3, the predicted concentration of uncharged formic acid doubles [131]. This unionized molecule can readily penetrate tissues and more readily partition into the CNS [133, 134]. Also, with worsening acidosis, further inhibition of cellular respiration, increasing hypoxia and lactic acid production will also worsen acidosis and again favor increased formic acid concentrations in a cycle termed “*circulus hypoxicus*” [130]. NaHCO_3 may be beneficial adjunct therapy for methanol poisoning due to its ability to affect formate ionization equilibrium and increase urine elimination [132]. Although the use of sodium bicarbonate as a sole treatment is insufficient to manage methanol intoxication, administration may be considered as an adjunct or temporizing measure in patients with metabolic acidosis following methanol ingestion or dermal exposure [130]. Large doses of sodium bicarbonate (e.g., 400–600 mmol (mEq) in the first few hours) may be necessary to significantly impact the metabolic acidosis [130]. Although the blockade of methanol metabolism through competitive inhibition of ADH and hemodialysis remain the mainstay of treatment, administration of NaHCO_3 in patients with serum pH <7.3 may be considered to attempt to correct the acidosis (LoE III) [135]. Administration of NaHCO_3 in patients with methanol toxicity will not prevent end organ damage and likely will

be insufficient to fully correct the metabolic acidosis. This topic is discussed in greater detail in ► Chap. 88, “Methanol and Formaldehyde.”

Sodium Bicarbonate for the Treatment of Uranium Nephrotoxicity

Uranium is an element commonly used as a fuel in nuclear power plants. With accidental or intentional exposure to uranium, nephrotoxicity and deposition into the long bones can be seen. Uranium rapidly reaches the systemic circulation and the majority is renally eliminated with subsequent accumulation in the renal proximal tubules. Tubular damage and necrosis can be seen in significant exposures due to the uranyl ion form. Urine alkalization favors binding of the uranyl ion to bicarbonate thereby decreasing the release of the toxic ion in the proximal tubule. The US National Council on Radiation Protection and Measurements recommends early decontamination strategies for persons exposed to uranium, including the administration of sodium bicarbonate either intravascularly or orally with a target urine pH of 8–9 [136]. One recent animal study evaluated the impact of one-time administration of oral NaHCO_3 on renal pH, excretion and deposition of uranium in renal tissues, renal function markers, and renal histopathology [136]. In the highest-dose treatment group (1 g/kg) the following effects were observed (versus placebo): (1) an increase in urine pH occurred at 2 h and was maintained for 9 h; (2) uranium excretion was significantly higher in the first 5 h following exposure but continued for 24 h; (3) the blood urea nitrogen and serum creatinine levels were significantly lower on days 3 and 7; (4) renal histopathology demonstrated no change on day 1, mild degeneration and necrosis on day 3, and mild and focally regenerated tubules on day 7 [136]. The role for NaHCO_3 administration for chronic exposure (e.g., uranium-laden well water) is unclear. In the event of an acute exposure to uranium, NaHCO_3 administration is recommended as soon as possible by oral or intravenous routes (or both) (LoE III).

Special Populations

Pregnant Patients

No specific trials have been conducted to evaluate the use of NaHCO_3 for the treatment of toxicity during pregnancy. Certain xenobiotics have demonstrated penetration of the placenta and subsequent toxicity in the fetus (i.e., salicylate and methanol) [137–139]. Toxic effects in the fetus may vary depending on gestational age and specific properties of the xenobiotic including molecular weight, lipophilicity, polarity, and protein binding (see specific xenobiotic for in-depth discussion). In general, stabilization of maternal hemodynamic and acid–base status will decrease the risk of spontaneous abortion or severe fetal compromise.

In a review conducted in the Toxicology Investigator's Consortium[®] (Toxic[®]) registry over a 3-year period, 103 (0.6%) of patients evaluated at the bedside by a toxicologist were pregnant. NaHCO_3 was used in 9 patients (13.2% of pregnant patients that received specific treatments). The indications for treatment with NaHCO_3 included TCA and salicylate toxicity. No specific maternal or fetal effects were reported; however, patients were not followed up to or beyond delivery [140]. In a recent review of the use of antidotes in pregnancy, NaHCO_3 was not included [141].

Treatment with NaHCO_3 is appropriate in pregnant patients experiencing toxicity from a xenobiotic with demonstrated resolution from this therapy (LoE III).

Pediatric Patients

Pediatric patients are at risk for accidental or intentional overdose from variable concentrations of high-risk medications, improper remixing of suspensions between doses, improper measuring tools (i.e., the use of a kitchen teaspoon), metabolic and physiologic differences, and exploratory ingestions to name a few. No trials have been conducted to evaluate the use of sodium bicarbonate in neonatal or pediatric patients. However, successful use of

NaHCO_3 in this population has been reported. The use of 4.2% NaHCO_3 (vs. 8.4%) in pediatric patients has been suggested given its lower osmolality but there is no evidence of superiority. Careful attention should be given toward ensuring the use of 2–3 mEq/kg of NaHCO_3 despite a change in concentration. Given the potential benefit and relatively low risk NaHCO_3 use is acceptable in pediatric patients demonstrating toxicity from the aforementioned xenobiotics (LoE III).

Administration Summary

Treatment with NaHCO_3 can include intravenous, inhalation, or, in rare select circumstances (e.g., uranium exposure), oral administration. The specific toxicity and treatment goal should be considered when choosing the optimum method of NaHCO_3 administration. When administering as an intravenous bolus, 2–3 mEq/kg is considered the starting dose, though higher starting doses and additional boluses may be necessary. In adult patients, the dose is rounded up to the nearest ampule (50 mEq) size; however, pediatric patients are dosed within the 2–3 mEq/kg range with repeated doses in all patients as necessary. In all patients requiring intravenous bolus dosing of NaHCO_3 , the drug is given IV push over 1–5 minutes.

When used as a continuous infusion, 150 mEq (3 ampules of 8.4% solution) is added to 850 mL of D5W with 20–40 mEq of potassium for a total quantity of 1000 mL. Adjustment of the total fluid volume in the bag to allow for the added 150 mL of volume from the NaHCO_3 solution is necessary to limit excessive free water. Additionally, the total concentration of NaHCO_3 in the solution will change from 150 to 130 mEq/L. D5W is the preferred base solution in order to avoid the hypertonicity associated with the addition of 150 mEq to the 154 mEq of sodium already present in 0.9% sodium chloride solution. In general, potassium should be administered along with bicarbonate to combat NaHCO_3 -induced hypokalemia due to a flux of potassium to the intracellular

compartment. Nebulized sodium bicarbonate can be prepared using mixture of 3 mL NaHCO_3 with 2 mL of 0.9% NaCl and administered using a standard nebulizer. Other concentrations have also been used, though no consensus exists on preferred concentration. Anecdotally, a more concentrated solution can precipitate in the nebulizer and patients report a foul salty taste.

Succimer is the generic name for meso-2,3-dimercaptosuccinic acid (DMSA).

History

In 1954, Froitzheim and Olligs [1] described the utility of the dimercaprol analogue DMSA in the chelation treatment of experimental mercuric chloride poisoning in mice. In 1957, Liang and associates [2] reported experimental evidence of the antidotal effects of the sodium salt of DMSA (sodium dimercaptosuccinate) against the toxicity of antimony-containing antiparasitic drugs, and in 1958, these Chinese investigators began the first clinical trials in humans [3]. Additional investigations showed the value of sodium dimercaptosuccinate in the treatment of other metal poisonings. In 1965, Wang and colleagues [4] reported its clinical use as an intravenous therapy for occupational lead and mercury intoxication. Okonishnikova [5] reported the utility of DMSA in experimental arsenic poisoning in the Soviet literature. A stable formulation of DMSA for the oral chelation of heavy metal poisoning was introduced in China in 1977 [6]. The clinical use of oral DMSA for lead poisoning was the subject of a report in the Western literature in 1978 [7]. Phase I clinical trials of DMSA were begun in the United States in 1980, and Graziano and coworkers [8] reported a dose-ranging study of DMSA in occupational plumbism in 1985. Phase II trials were conducted in lead-poisoned children [9].

Fig. 1 Chemical structure of succimer (*meso*-2,3-dimercaptosuccinic acid)

The generic name of DMSA is *succimer*. It has been approved for use in many countries. Under the trade name Chemet, oral DMSA was approved by the US Food and Drug Administration in 1991 as an orphan drug for the treatment of childhood lead poisoning.

Chemical Properties

Succimer ($C_4H_6O_4S_2$; molecular weight 182.2 g/mol) (Fig. 1) is a white crystalline powder that is soluble in aqueous alkaline solutions, such as 5% sodium bicarbonate. The vicinal thiol groups of the crystalline solid are relatively stable at room temperature. The drug has a mercaptan-like odor. Although succimer forms stable complexes with several metals in vitro, it may be several disulfide biotransformation products that are responsible for metal complexing action in vivo. A preformed complex of 1.2 mg of succimer and ^{99m}Tc has been licensed in the United States as a diagnostic agent for scintigraphic imaging of the renal parenchyma. The form of succimer marketed as a chelating agent (US brand name Chemet) is supplied as capsules containing 100 mg of succimer adsorbed onto inactive beads.

Pharmacodynamics

In addition to increasing excretion of toxic metals, such as lead, mercury, and arsenic, in human and animal studies, succimer has been associated with increases in the urinary excretion of zinc and copper in human trials [10–12]. Pharmacodynamic effects on cardiovascular, hepatic, or renal function have not been noted after oral administration.

Pharmacokinetics

Approximately 20% of orally administered succimer is recovered in the urine as the parent compound or metabolites in human studies [10, 13]. Although not definitive, the data on urine and fecal recovery are consistent with an oral bioavailability of approximately 20%. After absorption, greater than 90% of succimer in the blood is found in the plasma fraction, where it is highly bound (92%–95%) to plasma proteins (mainly albumin) by disulfide linkages [14]. Peak blood concentrations are reached in approximately 3 h. Most succimer seems to be distributed extracellularly. Minor amounts may penetrate erythrocytes [15], and some succimer transformation products are excreted in the bile and undergo enterohepatic circulation [13]. Succimer is excreted predominantly in the urine, where 80%–90% appears as mixed disulfides [10, 16]. In humans, approximately 70% of the mixed disulfide occurs as a 2:1 cysteine-DMSA adduct, 20% occurs as a 1:1 cysteine-DMSA adduct, and 10% occurs as cyclic disulfides of DMSA [16]. The increased urinary excretion of metals such as lead that follows administration of succimer parallels the urinary excretion of the mixed disulfides [10, 13]. The collective data suggest that it is a biotransformation product (or products) of succimer, and not the unaltered parent drug, that is responsible for its metal-mobilizing activity. The elimination half-life of transformed succimer is approximately 2–4 h. Some evidence suggests that renal clearance of the drug and its metabolites may be diminished in lead intoxication [12, 15] and that the higher the pre-chelation blood lead concentration, the smaller the percent decline in blood lead associated with a course of succimer treatment [17].

Contraindications and Precautions

Because succimer and its metabolites are excreted predominantly in the urine, the safety and utility of the drug in patients with severe renal insufficiency are uncertain. The intrarenal metabolism of succimer to the mixed disulfides that appear responsible for formation of metal chelates (see

above) may possibly be reduced in patients with renal insufficiency. It would be prudent to individually evaluate the utility of succimer in any patient with renal insufficiency by early and prompt laboratory assessment of metal mobilization. Limited experience yields no evidence that succimer can increase the hemodialysis clearance of toxic metals in anuric patients.

Succimer should not be administered to patients with a history of allergy to the drug. One case report [18] linked succimer with hemolysis in an adult with glucose-6-phosphate dehydrogenase (G6PD) deficiency. In an open-label clinical trial [19], five children with glucose-6-phosphate dehydrogenase deficiency tolerated succimer without incident. Therefore, if needed it is reasonable to administer succimer to G6PD-deficient patients as long as they are closely monitored for hemolysis (Grade III recommendation).

Succimer has fetotoxic effects when administered to pregnant rats at oral doses of 100 mg/kg/day [20] and teratogenic effects in pregnant mice at oral doses of 400 mg/kg/day [21]. However, chelation with succimer also has mitigated the adverse reproductive effects of several heavy metals in animal models [22, 23]. A report [24] described succimer chelation in a pregnant woman with a blood lead concentration of 44 µg/dL (2.1 µmol/L) at 29 weeks' gestation and subsequent succimer chelation of the neonate. The child exhibited no evidence of teratogenicity or overt drug toxicity. While it is reasonable to presume that use of succimer to treat overt or incipient metal-induced maternal toxicity may also benefit the fetus, potential benefit to the fetus in the absence of maternal toxicity is unclear. Oral chelation with succimer was used successfully to lower blood lead concentration in an asymptomatic 6-month-old infant with a blood lead concentration of 84 µg/dL (4.1 µmol/L) [25].

Adverse Effects

Succimer chelation generally is well tolerated. Patients should be advised that the drug may impart a mercaptan-like odor to the urine. During clinical trials, gastrointestinal symptoms (e.g.,

nausea, vomiting, or diarrhea) or mild, reversible serum transaminase elevation was observed in approximately 10% of patients. There were isolated reports of mild-to-moderate neutropenia. These adverse effects were not associated with succimer, however, in an open-label trial of 59 children [19] or a randomized, placebo-controlled, double-blind clinical trial of 780 children [26]. In a report of 3,180 courses of succimer chelation in 1,156 children treated for epidemic lead intoxication, no serious adverse effects attributed to the drug were observed [27]. A moderate increase in serum alanine aminotransferase that did not require discontinuation of therapy occurred in less than 1.5% of the children [27]. The manufacturer recommends monitoring serum transaminases at the inception of therapy and at weekly intervals. The drug should be stopped if there is an increase in ALT or AST ≥ 10 times above the upper limit of the reference range [28]. Rashes, some necessitating discontinuation of therapy, have been observed in approximately 4% of patients. Rare instances of drug-related mucocutaneous vesicular rash have been reported [17, 29]. A 3-year-old child tolerated a succimer overdose of 185 mg/kg without adverse effects [30]. During clinical testing in adults, succimer doses of 80 mg/kg were associated with an occasional report of mild-to-moderate drowsiness and mild abdominal disturbance [31]. An adult experienced no significant adverse effects after an intentional succimer overdose of 43–87 mg/kg [32].

Juvenile rats treated with a single 3-week course of oral succimer alone in the absence of prior or concurrent lead exposure demonstrated persistent deficits in learning, attention, and arousal that were similar in magnitude to those produced by high lead exposure [33]. In a different rat model, in utero exposure to succimer alone was associated with alterations in immune function in juvenile offspring [23]. The mechanism responsible for these persistent effects of early life exposure to succimer is uncertain but may involve detrimental succimer-induced changes in zinc and/or copper status. These observations reinforce the importance of considering potential risks and benefits before instituting treatment with succimer and other chelators [34].

Administration

In accordance with the Food and Drug Administration – approved regimen for lead poisoning – succimer has most often been administered at an oral dose of 10 mg/kg (pediatric dose, 350 mg/m³) every 8 h for 5 days, decreasing to 10 mg/kg (pediatric dose, 350 mg/m³) every 12 h for another 14 days. Repeat courses and extended dosing have been performed in some cases, depending on the patient's clinical status. Although sodium dimercaptosuccinate is not available in parenteral form elsewhere, in China, it has been administered intravenously (10% solution in normal saline) at daily adult doses of 1–2 g [4].

Thiamine (vitamin B1, thiamine, aneurin) (Fig. 1) is a water-soluble vitamin essential for the generation and utilization of cellular energy. Therapeutically, thiamine supplementation is used primarily for treatment of those who are thiamine deficient or at risk of deficiency. Thiamine is neither generated nor stored in large quantities; whole body stores in well-nourished individuals range from 30 to 50 mg, with hepatic stores of 2–4 mg [1]. Thiamine is found in leafy green vegetables, eggs, grain, and meats. Inadequate dietary intake is the most common cause of thiamine deficiency. The adult dietary requirement is 1–1.5 mg/day, and the thiamine content of many foods may be diminished by processing or heating [2]. Measures to avoid thiamine deficiency in the general population include enrichment of flour, cereals, and infant formulas [1–3].

Besides malnutrition, thiamine deficiency may result from malabsorption syndromes (including bariatric surgery), eating disorders, HIV/AIDS, chronic liver disease, folate deficiency, renal dialysis, and parenteral nutrition [4–11]. In developed countries, the most common reason for thiamine deficiency is poor oral intake and diminished thiamine absorption associated with chronic alcohol abuse [12]. Ethanol may decrease thiamine absorption by as much as 50% [1]. Thiamine deficiency may progress to the often missed or misdiagnosed syndrome of Wernicke's encephalopathy (WE).

The diagnosis of WE is clinical. Postmortem examination reveals a prevalence of WE (Fig. 2)

Fig. 1 Chemical structure of thiamine chloride

Fig. 2 Pathologic sample from a patient with Wernicke's encephalopathy showing necrosis of mammillary bodies (Courtesy of Pathology Learning Centre, Department of Pathology, University of Cape Town (www.digitalpathology.uct.za), with permission)

in up to 12.5% in chronic alcoholics, though as few as 20% of cases were diagnosed prior to death [13, 14]. Although earlier studies showed MR imaging to have a low sensitivity in detecting WE, later studies determined that FLAIR sequences or diffusion-weighted imaging may be helpful, especially in those patients with atypical presentation [15–17] (Fig. 3). The clinical syndrome of WE, first described in 1881, presents with the triad of mental confusion, ataxia, and ophthalmoplegia. The encephalopathic presentation of WE may range from apathy to profound confusion, which may be difficult to discern in patients suffering from ethanol withdrawal. The permanent neurologic manifestation of amnesia and confabulation was first described by Korsakoff in patients initially presenting with symptoms consistent with WE. The combination of these disorders is called Wernicke–Korsakoff syndrome

(WKS) in recognition of the fact that they are manifestations of the same disease. The ataxic component of WE may range from mild gait instability to a complete inability to stand [20]. Ophthalmologic manifestations reflect cranial nerve involvement; complete ophthalmoplegia is rare. Ocular abnormalities may include dysconjugate gaze and sixth nerve palsies, papilledema, and ptosis, though the most common presentation is nystagmus [9, 18, 19].

Thiamine deficiency, historically termed “beriberi,” has several different presentations. The neurological manifestations of WKS are often referred to as “dry” beriberi. “Wet” beriberi presents as cardiovascular disease, typically with high-output cardiac failure, predominantly right sided, although variations may occur, such as low output or biventricular [12]. A thiamine-deficient gastrointestinal syndrome of vomiting, abdominal pain, and lactic acidosis has been termed “gastrointestinal beriberi,” and peripheral neuropathy affecting lower extremity sensorimotor nerves more than upper, often painful, has been termed “neuropathic” beriberi [18–20]. Combinations of these various clinical syndromes may be present; whether they are distinct entities of thiamine deficiency or are simply part of the clinical continuum of the disease is unclear [19].

Thiamine is also used as an adjunct antidote in ethylene glycol poisoning. It serves as a cofactor in the conversion of glyoxylic acid (an ethylene glycol metabolite), by α -ketoglutarate glyoxylate carboligase to the nontoxic α -hydroxy- β -keto adipate. This is a minor pathway of glyoxylic acid metabolism, and, while shunting metabolism toward α -hydroxy- β -keto adipate is of theoretical benefit, there is no direct evidence that thiamine administration enhances glyoxylic acid metabolism or decreases ethylene glycol toxicity [21].

History

The relationship between beriberi and a nutritional deficiency was first described in 1885 though the syndrome of a deficiency causing paralysis of the hands and feet was described as

Fig. 3 This is neglected, alcoholic with complaints of ataxia with MRI features consistent with Wernicke's and cerebellar atrophy. Wernicke's encephalopathy is characterized by a quite distinct pattern of MR alterations, which include symmetrical alterations in the thalami, mammillary bodies, tectal plate, and periaqueductal area. In WE, the

blood–brain barrier is defective in the periventricular regions, in which there is a high rate of thiamine-related glucose and oxidative metabolism (MRI contributed by Dr Swati Shah and Dr Sumer Sethi, from Sumer's Radiology Blog (<http://sumerdoc.blogspot.com/2012/06/wernickes-encephalopathy-mri.html>) with permission)

early as 1611 in writings by Pieter Both, then Governor of the Dutch East Indies [2]. It was not until 1926 that the specific vitamin involved was isolated from rice polishings. The structure of thiamine was then elucidated in 1931, with the synthesis of thiamine being described in 1936, which enabled large-scale production [2].

Pharmacodynamics

Thiamine is an important cofactor in a number of metabolic processes. Conversion of thiamine to thiamine diphosphate and thiamine triphosphate occurs in the liver. Thiamine diphosphate, the active form of thiamine, is necessary for the

conversion of pyruvate to acetyl coenzyme A (ACoA) in the pyruvate dehydrogenase complex. This is the link between anaerobic glycolysis and the Krebs cycle. During glycolysis, two moles of pyruvate and two moles of adenosine triphosphate (ATP) are generated from every mole of glucose. Pyruvate and coenzyme A, with the cofactor thiamine diphosphate, form ACoA, which then enters the Krebs cycle, generating another 36 mol of ATP. In thiamine-deficient states, the accumulated pyruvate is converted to lactate, resulting in lactic acidosis [11, 12, 19]. Within the Krebs cycle, thiamine is also a necessary cofactor for the catalysis of α -ketoglutarate to succinyl coenzyme A. The lack of adequate thiamine stores causes a buildup of α -ketoglutarate, shunting conversion to favor formation of glutamic acid. The increased concentration of glutamate also contributes to the primary metabolic acidosis seen in thiamine-deficient states [12, 19].

In the pentose phosphate pathway, thiamine diphosphate is a cofactor for the enzyme transketolase, generating reduced nicotinamide adenine dinucleotide phosphate for further reductive biosynthesis, including formation of fatty acids [11].

Pharmacokinetics

Thiamine is readily absorbed in the proximal small intestine. Initially it was believed this active transport system was saturable and limited oral dosing. However, subsequent study demonstrated absorption also occurs via a passive process enabling large oral doses to be utilized [23]. In a study comparing equal oral and intravenous doses of thiamine, a multi-compartment model for absorption and distribution was demonstrated [24]. This conclusion was reached in measuring blood, plasma, and tissue concentrations of thiamine, thiamine monophosphate, thiamine diphosphate, and thiamine triphosphate. After IV administration, thiamine reached a peak plasma concentration in 2 min, with peak concentrations of thiamine diphosphate (the most active form) in 2–6 h; high

levels were maintained for up to 12 h. Following oral thiamine administration, almost complete absorption was seen in 40 min, with peak thiamine levels being achieved between 20 and 120 min and a return to baseline within 12 h. Thiamine half-life in plasma was determined to be 96 min or less [24, 25]. A study comparing equal oral and intramuscular thiamine doses concluded that oral dosing could produce almost equivalent concentrations as parenteral administration [26].

A more recent randomized, double-blinded, crossover study demonstrated that the thiamine passive absorption process is not saturable in oral doses up to 1,500 mg. Further, blood thiamine concentrations approaching those seen with IV administration were achieved within 1 week of initiating oral thiamine supplementation, despite the oral bioavailability of 3.7–5.3% reported in earlier studies [23, 27].

Adverse Effects

The overall safety profile of oral and intravenous thiamine is very good. One retrospective survey of 300,000 patient administrations identified no serious adverse reactions [28]. While rare, anaphylactic reactions to thiamine do occur [28–30], one study of 989 patients estimated the incidence of serious reactions to be only about 0.1% [31]. Thiamine is routinely given intravenously to patients believed to be predisposed to WE as a delay in administration may be life-threatening. With the low relative incidence of adverse reactions, it is considered good practice to administer thiamine without delay [32].

Special Populations

Pregnancy and Lactation

The US National Academy of Sciences recommended dietary allowances (RDAs) of thiamine during pregnancy and lactation are 1.4 and 1.5 mg, respectively [34]. Thiamine is classified by the US Food and Drug Administration as

pregnancy category A (safe) with dosing at RDA and category C (evidence of teratogenicity in animals but not in humans) if doses exceed the RDA. It is considered safe for use while breastfeeding [33].

Pediatric Patients

Recommended dietary allowance for birth to 5 years of age is 0.2–0.5 mg. Since there is no acute toxicity with larger doses, 1 mg doses may be used. Since thiamine deficiency has been seen in infant fed formula, caregivers should confirm that it is present in the formulation being used [10]. Thiamine deficiency may occur with malabsorption syndromes and food allergies and in breast-fed infants of a thiamine-deficient mother.

Geriatric Patients

This population may be at particular risk for thiamine deficiency. Poor intake and absorption, hepatic insufficiency, and ethanol abuse may all contribute to diminished thiamine stores. In noncritically ill thiamine-deficient geriatric patients, the recommended dose is 5–30 mg daily, in single or divided doses [34].

Dosing and Administration

The RDA in adults is estimated to be 1–1.2 mg, based on caloric intake [1, 34]. In a study evaluating dosing at nine large academic hospitals, the average daily dose was 100 mg, and the population most at risk for WE were most likely to receive oral dosing [35]. The following guidelines are based on the limited information available, the relative safety of large doses, and the adverse consequences of inadequate treatment; there are no good randomized clinical trials to guide clinicians on dose, frequency, or duration of therapy [36]. Those patients with low suspicion or for prophylaxis should receive a minimum of 100 mg, preferably intravenously (level III recommendation). Those who show any symptoms consistent with WE should receive doses of

>500 mg per day [19] (level III recommendation). Consensus guidelines recommend the administration of high (200–500 mg three times daily) oral or parenteral doses of thiamine for the treatment of WE, with a preference for parenteral dosing [3, 32, 37] (level III recommendation). Patients at risk for thiamine deficiency (malabsorption syndromes, dialysis patients, poor nutritional status, etc.) should receive 100 mg of parenteral thiamine in the ED, whether admitted or not, and continue with oral supplementation at the same dose when discharged [19] (level III recommendation).

The historical practice of thiamine administration prior to a carbohydrate load makes little pharmacologic sense. Thiamine uptake and enzyme system activation are much slower than glucose uptake. The negative impact of misdiagnosing a thiamine-deficient individual makes this practice worth continuing; thiamine administration at the recommend dose prior to a carbohydrate load should continue [38].

There is little evidence supporting thiamine administration in ethylene glycol poisoning [21]. There are animal models showing an increase in oxalate excretion in thiamine-deficient states in conditions of primary oxaluria which suggests that the minor pathway mentioned previously may be affected [3]. Thiamine's low adverse-effect profile with the potential of some benefits makes administration at standard doses worthwhile.

Thiosulfate is an inorganic compound used for a variety of medical and nonmedical applications. The antidotal use of thiosulfate stems largely from its powerful reducing capabilities, along with its ability to enhance endogenous enzymatic activity. Thiosulfate also exists naturally in humans, but at much lower concentrations than those found when used therapeutically. When used medicinally, it is virtually always in the form of its sodium salt.

History

Thiosulfate has a long history of use in industrial and medical settings. In industry, thiosulfate is used as an inorganic reducing agent for the production of finished materials [1]. Medical treatments using thiosulfate are quite diverse. Best known for the enhancement of rhodanese enzymatic activity in the mitigation of cyanide toxicity, thiosulfate has also been used in attempts at the treatment of toxic effects stemming from a variety of chemicals, including acrylonitrile, bromate, cisplatin, hypochlorous acid, paraquat, and platinum [2–9]. It is used topically in the treatment of selenium dioxide burns and is used as a treatment for cytotoxic drug extravasation involving cisplatin [10, 11]. A small amount of animal evidence supports the use of thiosulfate in hydrogen sulfide toxicity, although the exact mechanism is not clear [12]. Finally, thiosulfate has been studied and used in the treatment of several medical disorders, including tumor calcifications,

thromboangiitis, calcium nephrolithiasis, calciphylaxis, and tinea versicolor [7, 13–16].

that is joined to one or more sulfur atoms to enhance the activity of rhodanese) (Fig. 1) [21].

Properties

Sodium thiosulfate is a white, transparent crystal or powder. In nature it can occur in the anhydrous form, but it is found most often in the pentahydrate form and is unstable as a powder unless maintained under dry conditions [17]. When solubilized as a 1.5% or 9.76% solution, sodium thiosulfate is stable in normal saline, dextrose 5% water, and dextrose 5%/0.45% sodium chloride for at least 24 h.

Biochemically, this naturally occurring sulfur compound is strongly nucleophilic and also has appreciable redox activity. In humans, it is produced as a systemic metabolic intermediate derived from the amino acid cysteine, where it serves to protect against the depletion of reduced glutathione [18, 19].

Pharmacodynamics

Exogenous administration of thiosulfate results in a rapid elevation in its serum concentrations. The pharmacologic activity of sodium thiosulfate is hypothesized to develop more slowly, however, and to last far longer than the biologic half-life of the parent compound ($t_{1/2} \sim 20$ min). The increased duration of effect was demonstrated in a canine model in which a single dose of thiosulfate resulted in at least 1–2 h of protection from nitroprusside-induced cyanide poisoning [20]. The extended duration in pharmacologic effect is thought to be due to the occurrence of thiosulfate activity in the mitochondria and the slow intramitochondrial diffusion of $\text{S}_2\text{O}_3^{2-}$ ions. The mitochondria are the location of enzymatic rhodanese activity. Mitochondrial thiosulfate donates a sulfane sulfur (a divalent form of sulfur

Pharmacokinetics

Thiosulfate exists naturally in healthy humans at plasma concentrations of 1.1 ± 0.1 mg/dL. After exogenous intravenous administration of sodium thiosulfate to healthy humans, it has a calculated volume of distribution of 0.151 L/kg, with a clearance half-life of 0.25–3 h [22].

Sodium thiosulfate is metabolized partially in the liver to sulfate and also excreted partially unchanged by the kidneys [23]. The renal excretion data are contradictory. Some authors report that it is filtered solely through the glomerulus [24, 25]. Others report additional tubular secretion and reabsorption [26, 27].

Thiosulfate is reported to be eliminated using both a one-compartment and a two-compartment model [28, 29]. Its reported elimination half-life ranges from 16 to 182 min [28, 30]. Using a one-compartment model, $28.5\% \pm 9.4\%$ of the drug was recovered in the urine, with 95% recoverable in the urine within 4 h. The mean total body clearance was 190 ± 76 mL/min/ m^2 , and renal clearance was 50.4 ± 11 mL/min/ m^2 [29]. Using a two-compartment model, clearance was 1.39 mL/min, with urinary excretion of $42.6\% \pm 3.5\%$ of the dose at 180 min postdose and $47.4\% \pm 2.4\%$ at 18 h postdose [28]. The renal clearance of thiosulfate is sometimes used as a marker for inulin or glomerular filtration rate.

Special Populations

Pediatric Patients

Thiosulfate is used successfully to treat cyanide toxicity in newborns and children with sodium nitroprusside-associated cyanide toxicity

[31]. There is no reason that this population would respond differently than adults after administration of thiosulfate.

Pregnant Patients

The use of thiosulfate was studied in animal models in terms of thiosulfate's ability to cross the placenta and its ability to improve outcome clinically after poisoning. Although sodium thiosulfate did decrease toxicity from cyanide in the mother and fetus of gravid ewes, thiosulfate did not cross the placenta in this model [32, 33]. The implications of this finding are not clear, but may include the contribution of improvement of maternal outcome to the well-being of the fetus. Based on these data, thiosulfate should not be withheld on the basis of pregnancy.

Adverse Effects

Thiosulfate is generally well tolerated, even when administered to healthy patients in large doses. In dogs, hypotension is seen after overdoses of 500 mg/kg, but this has never been reported in humans [34]. Intravenous infusion of sodium thiosulfate can cause nausea, vomiting, localized burning, muscle cramping, and twitching at the injection site [35]. A single case of metabolic acidosis has been reported [36]. With certain analyzers, thiosulfate administration may falsely elevate plasma chloride concentrations potentially resulting in erroneous anion gap calculations [37].

Administration

There are no unusual contraindications or precautions when administering sodium thiosulfate. Thiosulfate must be administered intravenously because absorption from the gastrointestinal tract is poor. For cyanide toxicity in adults, the usual dose is 12.5 g administered intravenously over 10 min, repeated at half of the initial dose if required [38]. Although all current dosing information relies on bolus dosing, animal data suggest

that an infusion may be more effective [39]. While animal studies have suggested that there is no benefit in administering thiosulfate in addition to hydroxocobalamin for cyanide poisoning [40], there are reported human cases of both antidotes being administered concomitantly with favorable outcomes [41]. For protection of cisplatin nephrotoxicity, 12 g of thiosulfate is administered intravenously over 6 h, or 9 g/m² is administered as an intravenous bolus, followed by 1.2 g/m²/h intravenously for 6 h [42].

In children, the recommended dose for cyanide poisoning is 1 mL/kg of body weight using a 25% solution (250 mg/kg or approximately 30–40 mL/m² of BSA) not to exceed 50 mL (12.5 g) total dose [43].

Unithiol and *DMPS* are the commonly used generic terms for the compound 2,3-dimercaptopropane-1-sulfonic acid, sodium salt monohydrate.

History

The synthesis and metal-binding properties of 2,3-dimercaptopropane-1-sulfonic acid were reported by Petrunkin [1] in Kiev in 1956. By 1958, the agent had become available in the former Soviet Union as a pharmaceutical known as *unithiol* for the treatment of poisoning by certain heavy metals, particularly arsenic and mercury, as well as for other medical applications. In 1976, Heyl (Berlin, Germany) began marketing oral capsules of unithiol under the trade name Dimaval. Heyl has produced DMPS as a solution for injection (DMPS-Heyl) since 1991. Although it has not been approved as a pharmaceutical by the US Food and Drug Administration, DMPS has been included on the Food and Drug Administration's "list of bulk drug substances that may be used in pharmacy compounding" [2]. It is legally available for medicinal purposes in the United States.

Chemical Properties

Unithiol ($C_3H_7NaO_3S_3$; molecular weight 210 g/mol) (Fig. 1) is a crystalline solid that is freely soluble in water. It normally crystallizes as

Fig. 1 Chemical structure of unithiol (DMPS; 2,3-dimercaptopropane-1-sulfonic acid, sodium salt)

a monohydrate. The thiol groups are relatively stable but become increasingly subject to oxidation under alkaline conditions ($\text{pH} > 7$). In addition to their role in the formation of complexes with numerous metals, the vicinal thiol groups contribute antioxidant activity under certain conditions. The polar sulfonate group is responsible for the agent's water solubility, in contrast to the low water solubility of 2,3-dimercaptopropanol (dimercaprol), which has a terminal hydroxyl group. Although unithiol forms stable binary complexes with many heavy metals *in vitro*, the precise structure of its complexes with metals *in vivo* is a topic of ongoing investigation. When DMPS is administered to humans with elevated exposure to inorganic arsenic, a complex of DMPS with monomethylarsonous acid but not with inorganic arsenic appears in the urine [3, 4]. *In vitro* analysis has suggested that the primary complex of DMPS with inorganic mercury would result in two molecules of DMPS binding one molecule of mercury: $\text{Hg}(\text{DMPS})_2$ [5].

Pharmacodynamics

Rapid intravenous injection may have a vasodilatory effect causing transient hypotension; for this reason, intravenous injections should be administered slowly over 15–20 min. A moderate diuretic effect has been observed in animal studies. Unithiol has not been shown otherwise to affect renal or hepatic function at therapeutic doses. Unithiol increases the urinary excretion of copper and zinc, as shown in several animal and human studies [6]. Prolonged high-dose administration to dogs (150 mg/kg/day for 6 months) decreased the copper content of many visceral organs and was associated with anemia, presumably as a consequence of the copper deficiency [7].

Pharmacokinetics

The oral bioavailability of DMPS is approximately 50 % [8]. Peak blood concentrations occur at approximately 3.7 h [9]. Almost all of absorbed unithiol undergoes transformation in the plasma, mostly to DMPS-albumin complexes and to a lesser extent nonprotein-associated DMPS disulfides [10]. A small amount of DMPS may enter erythrocytes. Greater than 80 % of an intravenous dose is excreted in the urine, with an elimination half-life of 20 h. The form recovered in the urine exists as 10 % unaltered DMPS and 90 % transformed products, the latter consisting mostly (97 %) of cyclic polymeric DMPS sulfides, with minor amounts (2.5 %) as a DMPS-cysteine (1:2) mixed disulfide and acyclic DMPS disulfides (0.5 %) [10]. Experimental animal studies suggest that renal elimination of DMPS may occur via tubular secretion and that metals such as mercury are extracted from the renal tubular epithelium during this process [11]. Oxidized or reduced DMPS in the blood enters proximal tubular cells via renal organic anion exchangers (OAT1/OAT3), binds with intracellular Hg^{2+} , and is secreted as DMPS-Hg complexes into the tubular lumen via the multidrug resistance-associated protein 2 and possibly another transporter [12]. In normal human volunteers treated with DMPS, urinary mercury excretion correlated well with urinary excretion of DMPS and its disulfide metabolites [8].

Contraindications and Precautions

Because DMPS and its metal complexes seem to be excreted predominantly via the kidney, caution should be exercised when administering unithiol to patients with severe renal insufficiency. This may include initiating treatment at low dose (i.e., 3 mg/kg every 4–6 h) and closely monitoring patients for adverse effects and evidence of metal excretion (Grade III evidence). Unithiol has been used as an adjunct to hemodialysis [13, 14] and continuous veno-venous hemodiafiltration (CVVHDF) [15] in patients with anuric renal failure from mercury salts.

Unithiol has not been associated with teratogenicity. In a murine model, doses of 300 mg/kg/day during gestational days 6–15 showed no evidence of developmental toxicity. Unithiol has averted or diminished adverse reproductive effects of certain toxic metals in experimental studies [16]. Clinical experience in the use of unithiol during human pregnancy is unavailable. While it is reasonable to presume that the use of unithiol to treat overt or incipient metal-induced maternal toxicity may also benefit the fetus, potential benefit to the fetus in the absence of maternal toxicity is unclear.

Adverse Effects

Unithiol is generally well tolerated, with a low incidence (<4 %) of adverse side effects [17]. The most common adverse effects are allergic cutaneous reactions, such as exanthems or urticaria, which have resolved on discontinuation of the drug or lowering of the dose. Isolated cases of major allergic reactions, including Stevens-Johnson syndrome and erythema multiforme, have been reported [18, 19].

Administration

Unithiol can be administered by oral, intramuscular, or intravenous routes. In general, the intravenous route is reserved for treatment of severe acute intoxications by heavy metals (e.g., arsenic, mercury, or lead) in which compromised cardiovascular or gastrointestinal status may interfere with rapid or efficient absorption by the oral route. The daily intravenous dose for acute heavy metal poisoning is 20–30 mg/kg/day. One sixth of the daily dose should be administered every 4 h by slow intravenous infusion over 20 min. For oral chelation, a daily dose of 20 to 30 mg/kg/day can be administered in four divided doses (i.e., every 6 h). In some cases, protracted long-term treatment has been administered at a dose of 100 mg orally three times daily in adults or 50 mg orally three times daily in small children [17]. The pharmacokinetic and clinical database that forms the basis for various dosing regimens is

limited, and the foregoing dosages represent the author's recommendation based on the best available data (Grade III evidence).

Dopamine

Action and Structure

Dopamine (Fig. 1) exerts its action predominantly through the following three mechanisms:

1. *Dopamine receptor agonism*: Dopamine is an agonist for the dopamine receptor. Dopamine administration causes dopamine₁ (D₁) receptor-mediated vasodilation.
2. *β1-receptor agonism*: At doses higher than those required for D₁ receptor agonism (see subsequently), dopamine may cause stimulation of β₁-receptors.
3. *Generation of norepinephrine*: As shown in Fig. 2, dopamine is a precursor in the biosynthetic pathway of epinephrine and norepinephrine. Approximately 75% of an administered dose of dopamine is inactivated by either monoamine oxidase (MAO) or catechol *O*-methyl transferase (COMT), and only about 25% is stoichiometrically converted to norepinephrine. Because of this, norepinephrine-mediated α-receptor agonism is seen only when high doses (see subsequently) of dopamine are administered.

Based on animal data, it seems that dopamine does not cross the placenta, and it does not cross the blood–brain barrier except in preterm infants. Its volume of distribution has been reported to

School of Medicine, Aurora, CO, USA

Fig. 1 Chemical structures of dopamine, norepinephrine, epinephrine, and phenylephrine. Where indicated, the (*R*)-isomer, which possesses the most adrenergic activity, is shown

range from 1.81 to 2.45 L/kg, and dopamine's primary metabolite by MAO and COMT is homovanillic acid. Its half-life is approximately 2 min in adults, although it can be significantly longer in small children. Plasma dopamine concentrations are normally less than 100 pg/mL.

Dosage and Administration

Dopamine should be administered intravenously. Solutions may be prepared by mixing 200–800 mg of dopamine in 250–1000 mL of any standard intravenous solution.

Because of the various mechanisms by which dopamine acts, its effects depend on the dose administered. There are several possible ranges of doses, as follows:

1. *Low dose*: Doses ranging from 1 to 3 $\mu\text{g/kg/min}$ act primarily to dilate renal, intracerebral, mesenteric, and coronary vascular beds through activation of the D_1 receptor. At these doses, there tends to be little observed effect on most monitored hemodynamic parameters, although in some cases the vasodilation of these beds may cause a decrease in mean and diastolic blood pressure.
2. *Intermediate dose*: At doses ranging from 3 to 10 $\mu\text{g/kg/min}$, predominantly β_1 -receptor effects are seen. There is still an increase in D_1 -mediated blood flow in the above-described vascular territories and in the β_1 -receptor effects on the heart, resulting in an increase in heart rate, cardiac contractility, cardiac index, and conduction. At these doses, there may be modest increases in blood pressure but generally few effects on systemic vascular resistance (SVR), although small decreases in SVR, may be seen.
3. *High dose*: At doses greater than 10 $\mu\text{g/kg/min}$, the α -adrenergic effects from norepinephrine synthesis tend to predominate and may overwhelm the D_1 receptor-mediated vasodilation of the above-described vascular beds. Doses greater than 50 $\mu\text{g/kg/min}$ predictably cause severe vasoconstriction and generally should not be used.

Precautions and Contraindications

Because MAO is a major enzyme in the catabolism of dopamine, patients taking an inhibitor of this enzyme (see ► [Chap. 50, "Monoamine Oxidase Inhibitors"](#)) are expected to have a

Fig. 2 Biosynthesis of catecholamines

substantially exaggerated effect. It is generally recommended that doses of dopamine approximating one tenth of standard doses be administered in patients taking these agents. If these doses are ineffective, the dose can be titrated to the desired clinical effect. Because many dopamine preparations contain sodium metabisulfite, patients with sulfite allergies may develop allergic reactions to dopamine administration.

Epinephrine

Action and Structure

Epinephrine (see Fig. 1), a term applicable only to the L-isomer of 1-(3,4-dihydroxy phenyl)-2-methylamino ethanol, exerts its action predominantly through the following two mechanisms:

1. *β-Receptor agonism*: Epinephrine is an agonist at β-receptors causing an increase in cardiac index, contractility, conduction, and heart rate. At low doses (see subsequently), the vasodilating effects of β-receptor agonism predominate, resulting in a decrease in SVR and widening of the pulse pressure. Epinephrine is not an ideal first-line vasopressor except in cases of anaphylactic shock.
2. *α-Receptor agonism*: At higher doses (see subsequently), epinephrine has significant α-receptor agonism resulting in an increase in SVR and mean arterial blood pressure. These effects may result in a reflex decrease in heart rate.

Plasma epinephrine concentrations normally are 15–55 pg/mL. It is metabolized by MAO and COMT (Fig. 3). Its half-life is 2–3 min.

Dosage and Administration

Epinephrine is compatible with most standard intravenous fluid solutions. Autooxidation may occur in bicarbonate-containing solutions, however. It is generally constituted as a 1:1000 (1 mg/mL) or 1:10,000 (100 µg/mL) solution; 10 mL of 1:100,000 is equivalent to 1 mg. When given as a constant infusion, typically 1–2 mg is diluted into 250 mL (i.e., 4–8 µg/mL) of 5% dextrose in water or normal saline.

Epinephrine is best administered intravenously. If access is not immediately available, other routes are possible. It can be given subcutaneously, typically as a 1:1000 solution, but the effects are delayed and variable, particularly because of the local vasoconstriction it causes.

Fig. 3 Metabolism of norepinephrine and epinephrine by monoamine oxidase (MAO) and catechol *O*-methyltransferase (COMT). *DHPGAL* 3,4-dihydroxyphenylglycolaldehyde, *DHPEG* 3,4-dihydroxyphenyl ethylene

glycol, *DHMA* 3,4-dihydroxymandelic acid, *MHPG* 3-methoxy-4-hydroxyphenylethylene glycol, *VMA* 3-methoxy-4-hydroxymandelic acid, *MHPGAL* 3-methoxy-4-hydroxyphenylglycol aldehyde

Epinephrine also can be administered via an endotracheal tube in an emergent situation, whereby its pharmacologic effect is approximately half of that which would be achieved by intravenous administration.

In almost all circumstances in a critically ill patient, epinephrine should be infused intravenously, typically at doses ranging from 1 to 10 $\mu\text{g}/\text{min}$ (0.02–0.2 $\mu\text{g}/\text{kg}/\text{min}$) and subsequently titrated to the desired effect. At the lower end of this dose spectrum, β -adrenergic effects predominate. As the dose is increased,

α -adrenergic effects become evident and eventually predominate. The exact doses at which these effects occur in the individual patient are variable and should be determined based on the assessment of the clinical response.

Precautions and Contraindications

Patients on β -receptor antagonist therapy may have an exaggerated hypertensive effect after the administration of epinephrine due to unopposed

α -receptor agonism. In patients taking these agents, epinephrine should be used at the lowest possible doses, which can be titrated as necessary. This effect potentially is seen even with patients using β -receptor antagonist eye drops. Because patients taking tricyclic antidepressants or venlafaxine have reduced reuptake of sympathomimetic amines, their response to epinephrine may be exaggerated. Here too doses should start low and be titrated gradually to the desired clinical effect.

Because of a possible “catecholamine-sensitizing” effect of halogenated hydrocarbons on the heart, epinephrine and other β -receptor agonists should be used cautiously in patients poisoned by these agents. If it is necessary to use sympathomimetics such as epinephrine in these patients, therapy should be initiated at the lowest possible dose and titrated as necessary.

For patients with circulatory shock, the β_2 -adrenergically mediated decrease in SVR of epinephrine may be detrimental. Agents with predominantly α -adrenergic activity and few β_2 -adrenergic effects, such as norepinephrine or phenylephrine, are preferable.

Norepinephrine

Action and Structure

Norepinephrine (levarterenol) (see Fig. 1), a term applicable only to the L-isomer of 1-(3,4 dihydroxy phenyl)-2-amino ethanol, exerts its action predominantly through the following two mechanisms:

1. *α -Receptor agonism:* Norepinephrine is a direct-acting agonist at α -receptors and is predominantly used for this effect. Although it is a less potent α -receptor agonist than epinephrine, the lack of β_2 -agonism makes norepinephrine a preferable α -adrenergic vasoconstrictor (see later).
2. *β_1 -Receptor agonism:* Norepinephrine is a direct-acting agonist at the β_1 -receptor. Its agonistic properties at this receptor are roughly equal in potency to that of epinephrine.

Norepinephrine generally is used primarily for its α -receptor-mediated vasoconstrictive properties. As described earlier, it is preferable to epinephrine in this regard despite norepinephrine's lower potency at the α -receptor because of epinephrine's vasodilating effect secondary to its agonist properties at the β_2 -receptor. The net result of the administration of norepinephrine is an increase in SVR and mean arterial blood pressure.

Norepinephrine is metabolized by COMT and MAO. The product of COMT metabolism is normetanephrine, which is inactive. MAO action forms norepinephrine aldehyde, which is subsequently methylated by COMT to the inactive vanillylmandelic acid.

Norepinephrine generally is supplied as the bitartrate (Levophed); 2 mg of the bitartrate is equivalent to 1 mg of norepinephrine base. When specifying doses, it is important to be unambiguous about the bitartrate versus the base. It is preferable to express dosage in terms of norepinephrine base, and that convention is followed here.

Dosage and Administration

It is best to dilute norepinephrine bitartrate in dextrose-containing solutions because the latter inhibits its oxidation. It is generally prepared by adding 1 ampule (4 mg of norepinephrine base) to 250–1000 mL. Infusions should start at 0.5–1 $\mu\text{g}/\text{min}$ and should be titrated to the desired clinical effect. Pediatric infusion should begin at 0.05–0.1 $\mu\text{g}/\text{kg}/\text{mL}$ (or approximately 2 $\mu\text{g}/\text{m}^2$). Because of the powerful vasoconstricting effect of norepinephrine, it should not be given subcutaneously or intramuscularly, and precautions should be taken to prevent extravasation by its administration into large peripheral or central veins.

Precautions and Contraindications

As described earlier, it is important to avoid extravasation of norepinephrine. In the event of an extravasation, the local vasoconstriction should be treated by α -receptor blockade, which

Fig. 4 Transmembrane potentials of pacemaker cells of mammalian heart illustrating slowing of the rate of diastolic depolarization produced by vagus nerve stimulation (*darker curve*). Threshold is the potential for generation of

an action potential (From Smith CM, Reynard AM [eds]: Textbook of pharmacology. Philadelphia, WB Saunders, 1995, with permission)

can be accomplished by the administration of phentolamine. A typical dose is 5–10 mg of phentolamine diluted in 10–15 mL of normal saline administered through a fine needle; this should be infiltrated diffusely in the area of extravasation.

Patients taking guanethidine may have an exaggerated hypertensive effect from norepinephrine or other direct-acting α -adrenergic agonists because guanethidine decreases the uptake of these agents and may induce receptor supersensitivity. Patients taking amine uptake-inhibiting antidepressants, such as tricyclic antidepressants, also can be expected to have an exaggerated effect of direct-acting sympathomimetic amines such as norepinephrine secondary to decreased uptake. Patients taking any of the aforementioned agents should be treated with minimal doses of norepinephrine initially, which can be titrated to the desired clinical effect.

Phenylephrine

Action

Phenylephrine (Neo-Synephrine) (see Fig. 1) is primarily a direct-acting α_1 -adrenergic agonist and is devoid of activity at β -adrenergic receptors. It also seems to have a component of indirect action causing the release of dopamine and

norepinephrine. The latter activity is probably not responsible for its pressor effects, although it can have some significance for potential drug interactions, which are explained subsequently (Fig. 4).

When administered as a vasopressor, phenylephrine can be given intravenously, subcutaneously, or intramuscularly. The intravenous route is always preferred and except in extraordinary circumstances should be used exclusively when seeking a vasopressor effect. Phenylephrine's duration of action after intravenous use is approximately 15 min, in contrast to hours after subcutaneous or intramuscular injection. The long duration of action for these routes is probably the result of the delayed release from these sites because of phenylephrine's α -adrenergic vasoconstricting properties.

Approximately 16% of an intravenous dose is excreted unchanged. It is not appreciably protein bound. Its volume of distribution is reported to be 4.9 L/kg. Peak serum concentrations are generally in the vicinity of 200 ng/mL.

Dosage and Administration

Phenylephrine infusions generally are administered at a rate of 40–360 $\mu\text{g}/\text{min}$, although it is unusual to require dose rates greater than 180 $\mu\text{g}/\text{min}$.

The usual pediatric dose is 0.1–0.5 $\mu\text{g/kg/min}$. If needed, an initial bolus of 200–500 μg (5–20 $\mu\text{g/kg}$) can be given before the infusion.

If it is necessary to use the subcutaneous or intramuscular route, the usual adult dose is 2–10 mg repeated every 10–15 min. The pediatric dose is typically 0.05–1 mg/10 kg or 0.1 mg/kg (3 mg/ m^2) as a single dose. Because of the long duration of action of phenylephrine given by these routes, it should be administered only every 1–2 h.

Phenylephrine solutions for infusion generally are prepared by mixing 10 mg with 500 mL of any standard intravenous solution. For a more concentrated solution, 20 mg/500 mL may be used. When mixed with phenytoin, the solution may form precipitates.

Precautions and Contraindications

An enhanced pressor effect may be expected in patients taking guanethidine because of guanethidine's inhibition of phenylephrine uptake from the neuromuscular junction or possibly by adrenergic receptor hypersensitivity. Patients taking MAO inhibitors may be anticipated to have an exaggerated response to phenylephrine secondary to its indirect effects. In patients taking these agents, it is best to start with the lowest possible dose and titrate the dose as clinically indicated. Patients taking tricyclic antidepressants also may have an exaggerated response to phenylephrine, and they too should be treated with the lowest possible doses followed by a titration to clinical effect.

Grading System for Levels of Evidence Supporting Recommendations in *Critical Care Toxicology, 2nd Edition*

- I. Evidence obtained from at least one properly randomized controlled trial.
- II-1. Evidence obtained from well-designed controlled trials without randomization.
- II-2. Evidence obtained from well-designed cohort or case-control analytic studies, preferably from more than one center or research group.
- II-3. Evidence obtained from multiple time series with or without the intervention. Dramatic results in uncontrolled experiments (such as the results of the introduction of penicillin treatment in the 1940s) could also be regarded as this type of evidence.
- III. Opinions of respected authorities, based on clinical experience, descriptive studies and case reports, or reports of expert committees.
